### THE ACTION OF ULTRA-VIOLET LIGHT ON COLLOIDAL PLATINUM.

By ELLWOOD B. SPEAR, P. F. JONES, A. S. NEAVE AND M. SHLAGER.

Received December 31, 1919.

Considerable experimental work has been recorded in the literature on the curious and as yet unexplained coagulating action of ultra-violet,  $\beta$ , and X-rays on substances in the colloidal state.<sup>1</sup> Extraordinary as this effect appears, the case is still more complicated by the fact that these same rays have been employed by many investigators to produce certain hydrosols from the corresponding metals.<sup>2</sup> Moreover in some respects the evidence of one author often contradicts the results obtained by others, so that the entire subject is in a decidedly unsatisfactory state.

<sup>1</sup> Carey-Lea, "Kolloidales Silber und die Photohaloide." Doelter, "Das Radium und die Farben," Henri und Mayer, *Compt. rend.*, **138**, 521 (1903); Jorissen and Woudstra, *Z. Chem. Ind. Kolloide*, **8**, 8-11 (1911); Farmer and Parker, *This Journal*, **35**, 1524 (1913); Long, *Kolloid-Z.*, **14**, 130-8 (1914); Stintzing, *Kolloidchem. Beihefte*, **6**, 231 (1914); Schumm, *Kolloid-Z.*, **15**, 103 (1914); Nordenson, *Z. physik. Chem.*, **90**, 803-37 (1915); Pihlbad, *ibid.*, **92**, 471-95 (1917).

<sup>2</sup> Leonard and Wolf, *Ann. Phys.*, [3] **37**, 443 (1880); Svedberg, *Ber.*, **42**, 4375 (1909); Jaccquard, *Proc. Acad. Sci. Amsterdam*, **21**, 131-7 (1918).

It seemed desirable, therefore, to make a study of this interesting field and to correlate and harmonize, if possible, the conflicting evidence.

With this end in view it was decided to begin the investigation with

Fig. 1.—The ordinates represent the concentration of NaCl in millimols per liter in the reaction mixture. The abscissas represent the time in minutes necessary for the coagulation of one-half of the platinum in Solution B. Temperature of experiments = 20 to 22°. Curve I shows the results with the rays, Curve II without the rays.

as simple a case as possible, namely, the effect of ultra-violet rays on colloidal platinum, because the metals of the platinum group may be readily obtained in the colloidal state with a degree of purity greater than that of any other class of substances.

### Experimental Method.

In order to determine the effect of the rays a carefully prepared reaction mixture was divided into two parts. One of these was placed in a crystallizing dish upon the submerged stage of a cooling system described later, covered with a quartz plate, the stirring device started and the ultra-violet light turned on. The other half of the sample, contained in a second crystallizing dish, was either placed in a thermostat, or it was set beside the first one on the submerged stage and covered with a glass plate to cut off the ultra-violet rays. Thus the two samples were treated exactly alike except that one was subjected to the action of light plus ultra-violet rays, while the other was exposed only to the light that would penetrate glass.

All reaction mixtures were invariably made up to a definite volume, usually 25 cc., at the beginning of each experiment.

by diluting 20 cc. of the stock solution with conductivity water, or with a solution of electrolyte in case the latter was employed.<sup>3</sup>

**The Conductivity Water.**—The water employed in this work was redistilled from 0.02 *N* alkaline permanganate solution through block tin condensers. One sample of water, after standing for 3 months in a well-stoppered, hard-glass bottle, had a conductivity of  $4.10^{-6}$  mhos while another, immediately after it had been collected, had a conductivity of  $5.10^{-7}$  mhos.

**Platinum Solutions.**—Platinum hydrazols were prepared by the well-known electrical colloidation method according to Bredig.<sup>4</sup> The solutions were colored a rich brown and one of them at least was so stable that all the platinum had not settled out in two years' time. The concentration of the platinum in solution, determined by a method previously described by one of us,<sup>5</sup> is given in connection with the various curves.

The conductivity of the platinum solutions was, of course, greater than that of the water from which they were made. Platinum solution B, after standing for 3 months in a well-stoppered, hard-glass bottle, had a conductivity of  $1.2 \times 10^{-5}$  mhos. Platinum solution C, after standing for 2 months, had a conductivity of  $2.2 \times 10^{-5}$ .

**The Electrolytes.**—Colloidal platinum solutions are so sensitive to bivalent and trivalent ions, such as  $\text{Ba}^{++}$  and  $\text{Al}^{+++}$  that it was found more convenient to employ sodium chloride as the electrolyte during accurate measurements. Nevertheless, some runs were made with barium chloride solutions and results of the same general nature were obtained. The sodium chloride solutions were made from conductivity water and sodium chloride that had been specially prepared for analytical standardizations.

**Ultra-violet Light and Cooling System.**—The source of the ultra-violet light was a Cooper-Hewett 220-volt quartz lamp. This was enclosed in a wooden case which had the dimensions  $60 \times 90 \times 120$  cm. The front of the case was provided with swinging doors, and each door was fitted with a red glass window. By this means the operations could be watched without endangering the eyes, as red glass is particularly efficacious for cutting off the ultra-violet rays.

The lamp emits very considerable heat, so that a cooling system was necessary in order to maintain a constant temperature. This was secured by partially submerging the crystallizing dish containing the reaction mixture in a pneumatic trough placed inside the box. The trough was filled with water running at constant level.

<sup>3</sup> In some of our first experiments no quartz plate was used, so that the light was allowed to strike directly upon the surface of the liquid. During protracted runs of this nature, after 16 hours, small amounts of conductivity water were added from time to time in order to make up for the slight loss of water due to evaporation.

<sup>4</sup> Bredig, *Chem.*, 1898, p. 195.

NAL, 30, 195 (1908).

Another important factor to be considered is the distance of the surface of the reaction mixture from the source of light. This distance was maintained throughout our experiments at 15 cm. in order that the different runs might be comparable. Moreover, ultra-violet rays are absorbed almost entirely in the surface layers of the platinum solutions, so that it was necessary to stir the liquid in order to subject all portions to the action of the rays. This was effected by means of a small piece of platinum foil rotated by an electric motor.

**The End-point.**—If sufficient sodium chloride, which we will call the critical value, is added to cause the coagulation of platinum solutions within a few minutes, a change of color from brown to turbid gray takes place instantly on mixing the two solutions. The same change of color may be brought about by any amount of sodium chloride below this critical value, but a much longer time is necessary for the more dilute solutions of the salt. When these gray solutions are allowed to run through filter paper the filtrate is clear and colorless. During most of our work the experiment was allowed to proceed until such a clear colorless filtrate was obtained.

When very pure platinum solutions without added electrolyte were treated by the rays the time required for complete coagulation was sometimes as long as 20 to 30 hours. In such cases it was found more convenient to choose as the end-point the time necessary to reduce the color to that of a standard solution containing one-half the concentration of platinum possessed by the original reaction mixture. The standard solution was made by diluting a portion of the stock solution until the concentration of platinum was one-half that of the reaction mixture. The comparison of colors was made, of course, according to the usual colorimetric methods.

**Cleansing the Apparatus.**—All vessels that came in contact with the conductivity water or the platinum solutions were carefully cleaned with chromic acid, thoroughly rinsed with conductivity water and finally treated mouth downward for 30 minutes with steam from conductivity water.

### Discussion of Results.

For the sake of economizing space, only a few of our results are given in Tables I and II. The data for a single series of experiments, Solution B, Table I, have also been reproduced in the form of curves in Fig. 1. Information concerning the concentrations of colloidal and electrolytic solutions, also the temperature and the time of coagulation are given in connection with the tables and the curves. The time reported is the average of 2 to 5 separate determinations.

In any consideration of the results of our experiments it should be constantly borne in mind that the effect of the rays as shown by our data is relative and not absolute. The magnitude of the influence depends upon several factors which we have endeavored to hold constant, namely, the intensity of the rays, the distance that separated the reaction mixture from the source of the ultra-violet light, the rate and manner of stirring and the temperature. However, in spite of these reservations with regard to magnitude, three general conclusions of a qualitative nature may be drawn from the experimental evidence. These three conclusions will be discussed in order.

I. Ultra-violet light greatly hastened the coagulation of colloidal platinum without the addition of any electrolyte, except possibly the carbon dioxide of the air, or that due to the dissolution of the hard glass from the

container. This conclusion is justified by the fact that in Solution B the platinum was one-half coagulated by the rays in 10 hours, while without the rays the platinum was not completely coagulated in 2 years. In the case of another solution, not previously referred to in this article, which had a slightly different concentration, even a shorter time was required to coagulate one-half the platinum.<sup>6</sup>

II. The second conclusion is that when electrolytes are present their influence on the coagulation is very greatly accelerated by the action of the ultra-violet light. This is clearly brought out by a comparison of Cols. 2, 5 and 8 of Table I, with Cols. 3, 6 and 9, respectively. The acceleration is even more apparent in Fig. 1, where Curve I represents the concentration of the electrolyte in millimols per liter plotted against the time in minutes required for the coagulation of one-half of the platinum in Solution B, and Curve II represents the same thing for Solution B where the ultra-violet light was not employed.

III. A third conclusion to be drawn from our results is covered by the statement that the accelerating action of the rays is greater in dilute solutions of the colloid than it is in the more concentrated. This is clearly indicated by the ratios in Cols. 4, 7 and 10, Table I, at two different concentrations of sodium chloride 3.40 and 1.70 millimols per liter, and further substantiated in Table II for three different concentrations of the same colloidal solution where the electrolyte was kept constant.<sup>7</sup>

This result might be anticipated in part when it is remembered that the ultra-violet light can penetrate into the dilute solutions of the colloid farther than it can into the more concentrated. It is unsafe to conclude, however, that this is the sole reason for the observed facts. As suggested by Nordenson<sup>1</sup> it may very well be that the rays react upon the medium rather than on the platinum particles, in which case the accelerating action should be greater when there are fewer colloidal aggregates to absorb the ultra-violet light.<sup>8</sup>

<sup>6</sup> In order to determine whether or not the rays could coagulate colloidal platinum without the aid of some electrolyte other than water itself, it would be necessary to exclude the air during the distillation of the water, the formation of the colloidal platinum, and finally the treatment with the rays. The experiment would be difficult but not impossible.

<sup>7</sup> It is unfortunate that our work was permanently interrupted before the concentrations could be varied over a greater range.

<sup>8</sup> During the progress of work as yet unpublished it was found that the conductivity of sodium chloride solutions was slightly increased by the action of ultra-violet light. Minute quantities of hydrogen peroxide were also found to be present. Because these effects were so inappreciable it does not seem possible that the extraordinary acceleration of the rays can be attributed to these causes.

## Summary.

In this article we have presented experimental evidence to show that ultra-violet light will precipitate colloidal platinum out of solutions that are free from electrolyte except the carbon dioxide of the air, or that due to the dissolution of hard glass.

We have also shown that when electrolytes are present their precipitating effect is very greatly accelerated by the action of ultra-violet rays.

The action of the ultra-violet light was shown to be greater in dilute solutions of the colloid than in the more concentrated.

## THE APPLICATION OF IDEAL SOLUTION EQUATIONS TO DILUTE AQUEOUS SOLUTIONS.

BY JAMES KENDALL.

Received April 27, 1920.

The relative lowering of the vapor pressure of water by addition of a normal, non-volatile solute is such a fundamental point in the study of solutions that one would expect physical chemists, at this late date, to have agreed upon some definite theoretical treatment of the topic. An examination of the literature will show, however, that this is far from being the case. In the following pages a brief analysis of the present situation is made, and an explanation of existent discrepancies indicated. The erroneous interpretation now given to certain equations derived from the law governing vapor-pressure depression for ideal solutions, when applied to aqueous solutions, is also discussed.

**The Dilute-Solution Equation.**—Most introductory text-books<sup>1</sup> follow Arrhenius<sup>2</sup> in deriving the equation for the vapor pressure of highly dilute solutions from van't Hoff's gas law for osmotic pressure, obtaining the relation<sup>3</sup>

$$(p_0 - p) / p_0 = n / N \quad (1)$$

where  $p_0$  is the vapor pressure of pure solvent,  $p$  the vapor pressure of solution, and  $n/N$  is the ratio of the number of solute molecules to the number of molecules which the solvent would produce *if converted into*

<sup>1</sup> For example, Walker, "Introduction to Physical Chemistry," 1913, p. 193; Lehfeldt, "Physical Chemistry," p. 29.

<sup>2</sup> Arrhenius, *Z. physik. Chem.*, 3, 115 (1889).

<sup>3</sup> This relation is strictly valid only for solutions of infinite dilution, constituting the limiting case of the more exact equation:  $\ln (p_0/p) = n/N$ . The difference between the calculated values for the two forms of the equation is, however, inappreciable even for a fairly concentrated solution. For an example see Lehfeldt, *op. cit.*, p. 31.

*vapor*. The words in italics are vitally significant in the case of an associated solvent such as water.<sup>4</sup>

The experimental data for dilute aqueous solutions (although few determinations of a high order of accuracy are available) are in good agreement with the above equation. The results of Frazer and Lovelace<sup>5</sup> for mannite solutions may be cited:<sup>6</sup>

$T$ , °C.	Conc. (wt. molar).	$p_o - p$ , mm.	$p_o$ , mm.	$(p_o - p)/p$ , (obs.).	$(p_o - p)/p_o$ , (calc.).
20.008	0.4	0.122	17.548	0.070	0.072
20.036	0.5	0.156	17.578	0.089	0.089

**The Ideal-Solution Equation.**—The tendency in recent advanced textbooks<sup>7</sup> is to present the subject from a different standpoint, namely the ideal-solution equation.<sup>8</sup> This postulates that, above an ideal solution, the vapor pressure of each molecular species is proportional to its molar fraction in the solution, or,

$$(p_o - p) / p_o = n / (N + n), \quad (2)$$

where  $n$  and  $N$  represent the numbers of molecules of non-volatile solute and volatile solvent, respectively, *existent in the solution*. Although water is not an ideal but an associated solvent, it has been generally accepted that aqueous solutions may be treated as ideal, within the limits of experimental error, provided that the solute concentration is not too high.<sup>9</sup> Not only has the above ideal equation been extended to aqueous solutions, consequently, but formulas for the representation of osmotic pressure, freezing-point lowering and boiling-point elevation measurements have also been derived therefrom, which have been found to furnish very satisfactory agreement with the experimental data even for fairly concentrated solutions of normal solutes, where the deviations from the "dilute-solution equations" of van't Hoff are quite considerable.<sup>10</sup>

It is important to note the significance which has been attached by workers in these fields to the quantity  $N$  in the ideal equation (2) when applied to aqueous solutions.  $N$  has been almost universally regarded as still

<sup>4</sup> "It must be emphasized that the number of molecules  $N$  in the above equation does not denote the number of liquid molecules in the solvent, but only the number of gaseous molecules derivable from the liquid. This caution is necessary, because it has frequently been supposed that the equation enables us to determine the molecular weight of the liquid solvent, which is not the case." Walker, *op. cit.*, p. 194.

<sup>5</sup> Frazer and Lovelace, *THIS JOURNAL*, 36, 2439 (1914).

<sup>6</sup> For further examples see Jellinek, "Lehrbuch d. phys. Chem.," 2, p. 779 (1915).

<sup>7</sup> E. g., Washburn, "Principles of Physical Chemistry," 1915, p. 146.

<sup>8</sup> Van Laar, *Z. physik. Chem.*, 15, 457 (1894); Gibbs, *Nature*, 60, 461 (1897); G. N. Lewis, *Proc. Am. Acad.*, 43, 259 (1907).

<sup>9</sup> The approximate limits for solutes of various types have been indicated by Washburn, *op. cit.*, p. 141.

<sup>10</sup> See Findlay, "Osmotic Pressure," 1919, p. 65; Frazer and Myrick, *THIS JOURNAL*, 38, 1907 (1916).

representing the number of molecules of solvent actually existent in the solution.<sup>11</sup> Under this interpretation, since water is admittedly highly associated in the liquid state at ordinary temperatures, while water vapor is to all intents and purposes entirely monomolecular,<sup>12</sup> the value for  $N$  for any given solution must be quite different according to Equation 2 from what it is in Equation 1.

Now it is true that the essential incompatibility of dilute and ideal solution equations for solutions of finite concentration has long been recognized,<sup>13</sup> but it is also axiomatic that as the solute concentration approaches zero the divergences between them must be vanishingly small.<sup>14</sup> For an associated solvent such as water, however, the divergences between Equations 1 and 2, if  $N$  has *not* the same significance in each, are fundamental and persist right up to the very highest dilutions of solute. In other words, the ideal-solution equation, as it is at present being interpreted, is in utter disagreement with the dilute-solution equation for all aqueous solutions and hence cannot be in accordance with the existent experimental data. This is a point which has escaped attention hitherto,<sup>15</sup> but clearly one which requires immediate rectification.

**Reconciliation of the Ideal-Solution Equation with the Dilute-Solution Equation and with the Experimental Data.**—The necessary reconciliation can be effected by modifying the present erroneous interpretation given to Equation 2 when applied to aqueous solutions. Although liquid water is a mixture of associated molecules of the general type  $(\text{H}_2\text{O})_q$  and simple monomolecular  $\text{H}_2\text{O}$ , yet the latter molecular species is the only variety which is appreciably volatile

<sup>11</sup> An exception is found in the work of Washburn and Heuse, *THIS JOURNAL*, 37, 319 (1917). These investigators noted that it was necessary to employ a value "not appreciably different" from 18 for the molecular weight of water in deriving an equation for calculating osmotic pressures from vapor-pressure depression data.

<sup>12</sup> Kendall, *THIS JOURNAL*, 42, 2477 (1920); Menzies, *ibid.*, 43, 851 (1921).

<sup>13</sup> See, particularly, G. N. Lewis, *ibid.*, 30, 668 (1908). The ideal-solution equation is called by Lewis the "modified equation of Raoult," but since the name of Raoult has also been associated with the dilute-solution equation it has been thought advisable to avoid confusion here by giving the formulas under discussion impersonal titles. Raoult first expressed his experimental results by an equation similar in form to Equation 1 above, the subsequent modification to Equation 2 being made *empirically* to allow the equation to be extended to very concentrated solutions (see Ostwald, *Solutions*, 1891, p. 168-73).

<sup>14</sup> Thus Equations 1 and 2 for non-associated liquids obviously become identical when  $n$  is negligible in comparison with  $N$ .

<sup>15</sup> Presumably because the interest of investigators has been focused almost exclusively upon derived equations (osmotic pressure and freezing-point depression relationships) in which a factor which compensates for association is assumedly present, as will be discussed in a later section.

at ordinary temperatures.<sup>16</sup> Hence the vapor pressure  $p$  of any aqueous solution must be directly proportional, not to the total mol fraction of solvent present, but to the mol fraction of monomolecular  $\text{H}_2\text{O}$  existent in the solution. At ordinary temperatures this quantity is undoubtedly extremely minute,<sup>17</sup> owing to the high degree of association of water in the liquid state. On addition of solute it will be still further reduced, and at first sight this reduction would appear to follow quantitatively the current interpretation of Equation 2.<sup>18</sup> We must take into consideration the fact, however, that addition of solute also involves a shift in the equilibrium  $(\text{H}_2\text{O})_q \rightleftharpoons q(\text{H}_2\text{O})$ , a partial disassociation of complex to simple molecules taking place. The effect of this shift in the association equilibrium upon the vapor-pressure depression equation is examined below.

In pure water, let the mol fraction of non-associated  $\text{H}_2\text{O}$  equal  $N$ , and associated  $(\text{H}_2\text{O})_q$  equal  $1-N$ . In a solution, let the mol fraction of solute be  $n$ ; of  $\text{H}_2\text{O}$ ,  $N-x$ ; of  $(\text{H}_2\text{O})_q$ ,  $1-N-n+x$ .

For both solvent and solution we have, applying the mass-action law to the association equilibrium:  $(\text{conc. } \text{H}_2\text{O})^q / (\text{conc. } (\text{H}_2\text{O})_q) = K$ . Hence:  $N^q / (1-N) = (N-x)^q / (1-N-n+x)$ .

If sufficiently dilute solutions are considered, powers of  $x$  higher than the first can be neglected, and we obtain

$$x = nN / (N + q(1-N)).$$

But if the vapor pressure is due only to non-associated  $\text{H}_2\text{O}$ , its lowering will be proportional to the lowering of the mol fraction of non-associated  $\text{H}_2\text{O}$  in the solution; i. e.,  $(p_0 - p) / p_0 = x / N = n / (N + q(1-N))$ .

Since  $q$  is not known, it is impossible to evaluate this equation directly for any solution, but we can test its applicability by comparing it with the dilute solution equation. For, according to this equation, if  $a$ ,  $l$  and  $c$  be the numbers of molecules of solute,  $\text{H}_2\text{O}$  and  $(\text{H}_2\text{O})_q$  respectively in a given weight of solution  $(p_0 - p) / p_0 = a / (b + qc)$ . And since at high dilutions the shift in the water equilibrium will not significantly

<sup>16</sup> This is indicated by the normal behavior of water vapor (Kendall, *loc. cit.*). It is of interest to note that all of our currently accepted equations for aqueous solutions are derived with the use of the assumption that water vapor obeys the gas laws exactly, which cannot be valid unless water vapor is essentially monomolecular.

<sup>17</sup> Shown by the low vapor pressure of water at ordinary temperatures. From a comparison of the properties of corresponding organic derivatives, we may conclude that monomolecular  $\text{H}_2\text{O}$  should be more volatile than  $\text{H}_2\text{S}$ . Walden (*Z. physik. Chem.*, **55**, 683 (1909)) has calculated the boiling point for simple  $\text{H}_2\text{O}$  as  $-120^\circ$ . Van't Hoff ("Lectures on Theoretical and Physical Chemistry," Part III, p. 50) obtained a still lower value,  $-207^\circ$ .

<sup>18</sup> The ratio of the mol fraction of simple  $\text{H}_2\text{O}$  to the total mol fraction of solvent being regarded as a constant.

affect the *total* number of water molecules present, we have (within error limits),  $a/(b + qc) = n/(N + q(1 - N))$ .

Hence the ideal-solution equation is brought into agreement with the dilute-solution equation and consequently also with the experimental data for dilute aqueous solutions.

In applying ideal solution equations to dilute aqueous solutions we must, therefore, proceed just as if water were a non-associated liquid, the shift in the equilibrium  $(\text{H}_2\text{O})_q \rightleftharpoons q(\text{H}_2\text{O})$  compensating for the effect of association upon the molar fraction. In other words, it must be recognized that the ratio  $p/p_0$  is essentially independent of the association factor of the solvent. The effect of this on certain derived relationships may now be briefly considered.

**The Ideal Osmotic Pressure Equation.**—The failure of the dilute solution equation  $\Pi V = RT$  to represent the osmotic pressures of solutions of finite concentration is now generally conceded. In its place we have a more exact equation of the form:<sup>19</sup>

$$\Pi V_0 = -RT \ln(p/p_0) \quad (3)$$

where  $V_0$  is the molar volume of the solvent, a small correction factor for compressibility being omitted. To this equation the ideal solution principle that the ratio  $p/p_0$  represents the mol fraction  $x$  of volatile solvent has been applied, with the result:

$$\Pi V_0 = -RT \ln nx \quad (4)$$

In the application of this formula to dilute aqueous solutions, considerable energy has been expended in laborious calculations as to the effect of association.<sup>20</sup> The comforting conclusion has been reached that it makes little difference what value for the association factor for water is taken, since any variation in  $x$  (the mol fraction of solvent) on the right-hand side of the equation is counterbalanced by a corresponding variation in  $V_0$  (the molar volume of the solvent) on the left-hand side.<sup>21</sup>

In view of the result derived above, that  $p/p_0$  is independent of the association factor and that  $x$  is consequently a *fixed value*<sup>22</sup> for any given solution, this conclusion would appear to become invalid. Most fortunately (as it happens) a second error has been made which evens up matters. An examination of the thermodynamic cycle upon which Equations 3 and 4 are based<sup>23</sup> discloses the fact that  $V_0$  refers to the volume occupied by one

<sup>19</sup> Findlay, *op. cit.*, p. 55.

<sup>20</sup> For example, see Frazer and Myrick, *THIS JOURNAL*, 38, 1907 (1916).

<sup>21</sup> *E. g.*, with a weight-normal solution of cane sugar at 20° the values  $\Pi = 23.50$  for monomolecular water and  $\Pi = 23.64$  for water with an association factor 1.65 are obtained. The experimental value is  $\Pi = 26.64$  (Findlay, *op. cit.*, p. 64-5).

<sup>22</sup> The value obtained by "assuming" all water to be existent as monomolecular  $\text{H}_2\text{O}$ .

<sup>23</sup> See Washburn, *op. cit.*, 1915, p. 409-10.

gram-molecular-weight of *water vapor* after condensation, and is therefore also independent of the association factor for *liquid water*.

It seems almost impossible that such a fundamental point should not have been noticed before, but reference to recent literature will show that the "association factor" is still regarded as a stumbling block in the study of abnormalities in the osmotic pressure in aqueous solutions. Its removal from the sphere of action will, it is hoped, facilitate the long-delayed attack upon the main abnormality—hydration. The early workers<sup>24</sup> in this field have certainly met with more than their fair share of good fortune in the fact that their assumptions, although founded upon a wrong basis, are practically valid as a consequence of the mutual cancellation of the two errors involved.

**The Ideal Freezing-point Depression Equation.**—In the application of the ideal solution formula—

$$\ln x = (Q/R) \cdot (1/T - 1/T_0) \quad (5)$$

for freezing-point depressions, similar mistakes have been made.  $Q$  (the molar heat of fusion) has been regarded as a factor varying with association, although as derived in the thermodynamic cycle it refers to one gram-molecular-weight of *condensed water vapor*. In the same way  $x$  is considered as a variable,<sup>25</sup> compensating for variations in  $Q$ . In actual fact, both  $x$  and  $Q$  are *independent* of association in the liquid state, and all values derived with the use of arbitrary association factors (even though they differ but slightly from the correct values) are misleading.

### Summary.

The essential incompatibility of the fundamental ideal-solution equation, as applied at present to dilute aqueous solutions, with the dilute-solution vapor-pressure depression equation and with the results of experiment has been pointed out.

It has been shown that the discrepancy disappears when due notice is taken of the fact that the vapor pressure of water at ordinary temperatures must be ascribed practically entirely to its monomolecular fraction, the shift in the equilibrium  $(\text{H}_2\text{O})_g = q(\text{H}_2\text{O})$  on addition of solute counterbalancing the effect of the association upon the molar fraction.

Some fundamental errors in the present application of ideal osmotic-pressure and freezing-point depression equations to dilute aqueous solutions have also been corrected.

## THE CONCENTRATION OF THE ERBIUM EARTHS.

BY PAUL H. M.-P. BRINTON AND C. JAMES.

Received September 16, 1920.

An investigation of four different methods for the concentration of the less basic rare earths resulted in the discovery of two of the most rapid procedures for this purpose. The methods examined were (a) formation of basic nitrates; (b) crystallization of chlorides from 1:1 hydrochloric acid; (c) formation of basic chlorides; and (d) formation of basic thio-sulfates. Of these methods (a) and (b) proved to be the best, and the exact manner in which they were carried out is described below.

(a) **Formation of Basic Nitrate.**—When following the old plan involving fusion of the nitrate for separating erbium from yttrium, it has been pointed out from time to time that the best results were obtained when the entire melt went into solution in boiling water, and deposited the basic nitrate in small crystals upon cooling or evaporation. The basic nitrates are more soluble in hot dilute solutions and less soluble in hot concentrated or cold dilute solutions. However, when the mixture consists mainly of the erbium earths, the basic nitrate, if there is much of it, will remain insoluble. The fact that the best results were obtained when the basic nitrate dissolved entirely in the excess of nitrate solution makes it obvious that the same results should be obtained by treating the solution with sodium hydroxide solution.

In order to test this a solution of yttrium nitrate, containing a little erbium, was heated to boiling, treated carefully with a fairly strong solution of sodium hydroxide and thoroughly boiled. The yttrium hydroxide which first precipitated soon dissolved. The addition of the sodium hydroxide solution was continued until minute crystals of the basic nitrate were observed swirling through the liquid. The whole was then set aside to cool. Upon examining the vessel next morning it was found to be lined with a mass of needle-like crystals of the basic nitrate radiating towards the center. These were filtered off, dissolved in the least amount of nitric acid, and the solution heated to boiling and treated with sodium hydroxide solution as described above. The basic nitrate crystals from this solution dissolved in nitric acid giving a rose-red solution showing intense absorption bands of erbium. This, together with a determination of the equivalent, showed that erbium was rapidly collecting in this portion.

The original filtrate was treated several times with sodium hydroxide solution. Although the concentration of the nitrates was kept high, the absorption bands soon began to fade.

Since this method worked so well for the yttrium-erbium mixture, it was next tried out with yttrium, holmium and erbium with good results.

During the fractionation, fractions of the same rare earth content were mixed together. Fractionations of this type are intermittent and do not run so smoothly as the simple crystallization methods. After further work it was noticed that two kinds of basic nitrates were obtained, one as described above, and another which separated from the boiling liquid during evaporation. The former compound readily dissolved in the diluted mother liquor at the boiling point, while the latter did not.

Some of the basic nitrate and a solution of the nitrates which appeared to be of the same rare earth content were next selected. The nitrate solution was diluted somewhat, heated to boiling, the basic nitrate gradually added and the clear solution evaporated to the original volume and allowed to cool. After standing for some time, a quantity of basic nitrate separated out which, when examined in the spectroscope, showed as great an increase in the erbium content as the former sodium hydroxide fractionation or the old classic fusion of the nitrate gave.

It must be admitted that this method when used with the fractional crystallization plan requires much more practice than the crystallization of double nitrates, bromates or ethyl-sulfates. However with a little experience the time saved is very great.

(b) **The Crystallization of the Chlorides.**—For the concentration of the more basic erbium earths, holmium and dysprosium from yttrium, the authors recommend the fractional crystallization of the chloride from constant-boiling hydrochloric acid. The speed of separation was first observed during the preparation of a chloride from an yttrium oxide containing some holmium and dysprosium. The solution of the chlorides was evaporated, cooled in snow and saturated with hydrogen chloride for 20 to 30 minutes. The crystals which formed were removed by suction, the filtrate was again saturated with hydrogen chloride, the crystals were removed, and the whole process was repeated several times. When the final mother liquor was examined it was found to consist of fairly pure yttrium chloride.

The first crystals which were precipitated were then further fractionated by dissolving in water containing a little hydrochloric acid, evaporating until rather thick, cooling by placing the container in snow and saturating with hydrogen chloride. The precipitated crystals were again dissolved in water and the same operations repeated several times. Since the chief interest lay in the least soluble portion, the mother liquors were placed aside each time. The following diagram shows the exact number of fractions that were taken.

Fraction 2e when dissolved in water showed very strong holmium bands while those of erbium could just be distinguished. The solution was precipitated by oxalic acid, the oxalate ignited to oxide and the equivalent determined.

The mother liquor 3h, which showed only a weak absorption of holmium, etc., was subjected to a double precipitation with oxalic acid. After ignition the equivalent of this fraction was also determined.

No. of Fraction.	I.	II.	Average	At. Wt.
2e	126.5	127.9	127.2	
3h	90.2	90.1	90.2	

Dennis and Dales<sup>1</sup> worked with the hydrogen chloride precipitation method for the fractionation of the yttrium earths. In this case a solution of  $MCl_3$  was concentrated and precipitated in ice-salt freezing mixture by passing in hydrogen chloride for 5 hours. The mother liquor was precipitated by ammonium hydroxide, dissolved in hydrochloric acid and again precipitated by hydrogen chloride. The original solution and the fractions were then compared as to spectra, and no change in the relative intensities of the spectra was observed. On this evidence Dennis and Dales rejected the method.

Since the use of hydrogen chloride is troublesome and unpleasant and moreover since the crystallization occurred mainly where the gas came in contact with the solution, it was thought that crystallization from 1:1 hydrochloric acid would be very much simpler and more effective.

All fractions except 2e and 3h from the preceding operations were combined, boiled down to hydrochloric acid of constant boiling point, and fractional crystallization was started. The solutions were evaporated until a scum formed on the surface, when they were allowed to stand for from 15 to 20 hours. Simple decantation was used instead of filtering and washing as was done with the hydrogen chloride method. By the time the tail fraction had become No. 9 the head fraction had become No. 4, owing to the combining of the small head fractions to obtain enough to work with. The atomic weights of these two fractions were then determined, and found to be 92.5 and 124.0, respectively.

<sup>1</sup> Dennis and Dales, *THIS JOURNAL*, 24, 421 (1902).

The crystals and mother liquor from Fraction 7 were next examined in order to find out the speed of separation given by one crystallization. The oxide from the crystals weighed 14.36 g. and the oxide from the mother liquor weighed 39.35. The atomic weight of the oxide from the crystals was found to be 106.1, while that from the mother liquor was 99.8.

After the above tests were made the fractionation was continued for 4 more operations, and the atomic weights of the extremes determined. The head fraction, No. 4, gave 133.70 while the tail fraction, No. 12 gave 91.5.

The absorption spectra were then examined by dissolving 1-g. portions of oxide from various fractions in equal amounts of nitric acid and diluting to the same volume in each case. Fraction 4 gave intense lines of holmium. The crystals from Fraction 7 gave fairly strong lines of holmium, while Fraction 12 gave only very faint lines of this element. Erbium was found to concentrate in the most soluble fractions with the yttrium. This indicated that erbium chloride was more soluble.

To follow the course of the small amount of dysprosium, Fraction 12 was concentrated and more of the solid was added until the holmium spectra in No. 4 and No. 12 were of about the same intensity. By comparing the intensity of the two faint dysprosium bands with that of the middle holmium band, it was estimated that in Fraction 12 the holmium band was 4 times as strong as the dysprosium bands, while in Fraction 4 the holmium was perhaps twice as strong as the two dysprosium bands. This indicated that relatively the dysprosium was twice as concentrated in No. 4 (the least soluble fraction) as it was in No. 12 (the most soluble fraction).

The order of separation in line of decreasing solubility of the chlorides would accordingly run: erbium, yttrium, holmium, dysprosium.

(c) **Basic Chlorides.**—In the case of the basic chloride, the crystals from Fraction 8 of the preceding experiment were dissolved in water, and ammonium hydroxide was added until a fair precipitate was obtained. The mixture was then heated and concentrated until the character of the hydroxide was changed into a granular basic chloride. Five fractions of about equal size were obtained, and of these Fraction 1 gave an atomic weight of 105.6 while Fraction 5 gave 93.4.

(d) **Basic Thiosulfates.**—These precipitates were obtained in the following manner. The boiling chloride solution was treated with very dil. ammonium hydroxide so long as the precipitated hydroxides would dissolve on continued boiling. A solution of sodium thiosulfate was then added, when the basic thiosulfates were immediately precipitated. The precipitate was filtered off, and the whole process repeated. Four fractions were obtained. The head fraction, No. 1, gave an atomic weight of 97.1, while the tail fraction, No. 4, gave 91.0,

### Summary.

The authors highly recommend the basic nitrate method in the two forms herein outlined for the separation of erbium, holmium, dysprosium and the less basic earths from yttrium; and the crystallization of the chlorides from 1:1 hydrochloric acid for the separation of holmium and dysprosium from yttrium.

## OXIDATION AND REDUCTION OF HYDROQUINONE AND QUINONE FROM THE STANDPOINT OF ELECTROMOTIVE-FORCE MEASUREMENTS.

By F. S. GRANGER AND J. M. NELSON.

Received October 23, 1920.

Very little work has been done on the study of oxidation and reduction from the standpoint of potential measurements, in the field of organic chemistry, and nearly all of that has been of an empirical character. Bancroft<sup>1</sup> included in a study of a large number of more or less common oxidizing and reducing agents, alkaline solutions of hydroquinone and pyrogallol. The proportions used in making up these solutions were not given, but had they been, they would not have thrown much light upon the composition of the resulting mixtures, since both hydroquinone and pyrogallol are very unstable in alkaline solutions. Furthermore, the potentials were not measured against any standard electrodes, but against other oxidizing and reducing agents. Neumann<sup>2</sup> later put Bancroft's results on a more definite basis by comparing them with a calomel electrode. Baur<sup>3</sup> determined the potentials manifested by solutions made up of definite amounts of hydroquinone and formaldehyde, in aqueous sodium hydroxide. Slaboszewicz<sup>4</sup> made some admittedly rough measurements on aldehyde and alcohol in 2*M* sulfuric acid. Mathews and Barmeier<sup>5</sup> published some potentials of various photographic developers and Frary and Neitz<sup>6</sup> carried out a more elaborate study along the same lines as those of Mathews and Barmeier. All of these measurements were determinations of potentials of solutions, made up with definite concen-

trations of the components but without any reference to the reaction taking place or the products formed, so that the results, while interesting in some cases from the technical side in showing the reducing powers of these particular solutions, are still of little scientific significance.

Haber and Russ<sup>7</sup> in a study of the electrolytic reduction of some organic compounds, such as nitrobenzene and quinone, observed that when the potential of a platinum electrode immersed in a quinone-hydroquinone solution was measured against a calomel electrode it behaved similarly to an ordinary metal electrode immersed in a solution of one of its salts. They considered the reaction which takes place in the quinone-hydroquinone solution to be

and compared the difference in the observed potentials of any two solutions with the corresponding difference in calculated values, obtained by means of Equation 3

$$\pi_1 - \pi_2 = \frac{RT}{2F} \left[ \ln \frac{(\text{Quinone})}{(\text{Hydroquinone})_1} - \ln \frac{(\text{Quinone})_2}{(\text{Hydroquinone})_2} \right]. \quad (3)$$

Equation 3 is the usual van't Hoff Equation 2

$$\pi = \frac{RT}{2F} \left[ \ln \frac{\text{Quinone} \times [\text{H}^+]^2}{\text{Hydroquinone}} - \ln K \right] \quad (2)$$

so modified as to avoid taking into account in the calculations the acidity of the solutions. This is of course possible by keeping the acidity the same in all the experiments. They found that the calculated and observed differences, obtained in this way, agreed quite well. Due to this agreement they concluded that the van't Hoff Equation 2 was applicable, and that this organic reaction was similar in character to oxidation-reduction reactions occurring in the case of electrolytes.

As is well known, quinone and hydroquinone combine, reversibly, in solution to form quinhydrone, and as no data as to the extent of this combination were at hand the actual or relative concentrations of quinone and hydroquinone in Haber and Russ's solutions, which were prepared by adding known excesses of either one of these substances to a solution of quinhydrone, were unknown and undetermined. There exists, therefore, one important assumption in their method of reasoning which requires additional experimental data before it can be considered as justified. Haber and Russ assumed on the one hand, that the van't Hoff equation was applicable and therefore the quinhydrone must have been practically completely dissociated, and on the other hand, that since the quin-

<sup>7</sup> Haber and Russ, *Z. physik. Chem.*, 47, 257 (1904).

hydrone was completely dissociated and therefore the concentrations of quinone and hydroquinone known, the van't Hoff equation was applicable.

In the present investigation the determination of the actual concentrations of the reactants was undertaken and the study was extended to varying hydrogen-ion concentration as well. By the use of the data obtained it has been possible to show, without resorting to any assumption as to the degree of the dissociation of the quinhydrone as Haber and Russ did, that the calculated values, using Equation 3, for the differences in the electromotive-force measurements of any two solutions of different concentrations of quinone and hydroquinone, agree with the corresponding experimental values. Furthermore, having determined the actual concentrations of the reactants, quinone, hydroquinone and hydrogen ion, it has been possible to calculate also, by means of Equation 2, the potential of each solution and to show that this calculated value agrees with the experimental value, when the difficulties in determining the exact concentrations of the reactants and resultants of the reaction are taken into consideration and when it is borne in mind that the van't Hoff equation is based on the ideal gas laws and osmotic pressure rather than upon concentration. This method is therefore more satisfactory and direct for ascertaining the applicability of the van't Hoff equation than that of only comparing the differences between the potentials of two solutions with the corresponding calculated values.

### Determination of the Concentrations of the Reactants and Resultants.

**Solubility of Hydroquinone.**—Since no data on the solubility of hydroquinone at 25° could be found in the literature, solubility determinations were made.

TABLE I.

G. per 100 cc. of Solution.

Solvent.	1.	2.	3.	4.	5.	Av.	Moles per liter.
Water.....	7.094	7.091	7.112	7.086	...	7.10	0.645
0.01M HCl.....	7.060	7.128	7.136	7.028	7.146	7.10	0.645
0.1 M HCl.....	6.978	6.944	...	...	...	6.96	0.633
1.0 M HCl.....	5.436	5.442	...	...	...	5.44	0.494

Because the hydrogen ion is considered as one of the resultants in the reaction, Equation 1, various amounts of hydrochloric acid were added. The hydrochloric acid also served to make the solutions good conductors, which of course is necessary. It will be noticed in the table that the hydrochloric acid decreased the solubility of the hydroquinone.

**Solubility of Quinone.**—The solubility of quinone in water at 25° had been determined previously by Luther and Leubner<sup>8</sup> using the analytical method of Valeur<sup>9</sup> which consisted in titrating the liberated iodine with thiosulfate. In this way they found the solubility of quinone to be 1.265 moles per liter, a value in which there is evidently an

<sup>8</sup> Luther and Leubner, *J. prakt. Chem.*, 85, 314 (1912).

<sup>9</sup> Valeur, *Compt. rend.*, 129, 552 (1899).

TABLE II.

Solvent.	Moles per liter.		G. per 100 cc.
	1.	2.	
Water.....	0.1266	0.1266	1.37
0.1 <i>M</i> HCl.....	0.1275	0.1275	1.38
1.0 <i>M</i> HCl.....	0.1332	0.1332	1.44

error in the placing of the decimal, since the value we obtained by repeating the determination is just one-tenth of theirs.

Here again it is to be noticed that the hydrochloric acid influences the solubility, but in the opposite direction from that observed in the case of hydroquinone.

**Solubility of Hydroquinone and Quinone in the Presence of Each Other.** Solubility of Quinhydrone.—It was not possible to make up solutions containing known concentrations of both hydroquinone and quinone by simply dissolving weighed quantities of these substances in a measured volume, because they combine immediately in equimolar proportions to form quinhydrone. Furthermore, since in solution the quinhydrone exists in mobile equilibrium with them their concentrations cannot be determined directly, by analytical means. For the series of solutions (see below), in which only the hydrogen-ion concentration varied, the concentrations of either hydroquinone or quinone were fixed by saturating the solutions with one of them and quinhydrone. A solution saturated with both was not possible owing to the slight solubility of the quinhydrone, which separated out when only a small quantity of quinone was added.

In order to prepare solutions containing known concentrations of the reactants it was necessary to know not only their solubilities and that of quinhydrone but also the degree of dissociation of the latter into its components, hydroquinone and quinone.

Luther and Leubner determined the solubility, in water, of the undissociated quinhydrone and also its dissociation constant by a method similar to that used by von Behrend<sup>10</sup> for the phenanthrene picrates. They saturated water and aqueous hydroquinone solutions of known concentrations with quinhydrone at 25°, and determined the total quinone, combined and free, present in the filtrate by Valeur's method, which is applicable owing to the complete dissociation of the quinhydrone as the quinone is removed by the iodide. This total quinone represents (formula-weight for formula-weight) the total quinhydrone, dissociated and undissociated, which was dissolved in saturating the solution. If *s* is the solubility of the undissociated quinhydrone, *a* the solubility of the undissociated and dissociated quinhydrone, *b* the known excess of hydroquinone added, *h* the actual concentration of hydroquinone, *q* the actual concentration of quinone, all in formula-weights per liter, then the free and combined hydroquinone in the solution, which is the same in moles as the total quinhydrone (dissociated and undissociated) or *a*, plus the added excess of hydroquinone, *b*, is equal to the hydroquinone combined in the undissociated quinhydrone, *s*, plus the free hydroquinone, *h*, in the solution; or

$$a + b = s + h; \text{ or } h = a + b - s \quad (4) \text{ and } (5)$$

The total quinone (free and combined in the form of quinhydrone) in the solution, *a*, determined by titration, is equal to the undissociated quinhydrone, *s*, plus the free quinone, *q*; or

$$a = s + q; \text{ or } q = a - s \quad (6) \text{ and } (7)$$

<sup>10</sup> von Behrend, *Z. physik. Chem.*, 15, 183 (1894).

The dissociation constant,  $K$ , of the quinhydrone, assuming that the mass law holds in this case, can be represented as

$$K = (q \times h)/s; \text{ or } Ks = q \times h \quad (8)$$

Substituting in (8) the values for  $q$  and  $h$ , from Equations 7 and 5 respectively, then

$$Ks = (a - s)(a + b - s) \quad (9)$$

If the experimental precision were fine enough,  $s$ , and  $K$ , in Equation 9, could be calculated from any pair of determinations by means of simultaneous equations, since  $a$  and  $b$  are measured quantities. But comparatively slight deviations from these ideal conditions render this method of calculation inapplicable, so that recourse must be had to a method of trial and approximation which Luther and Leubner carried out in the following way.

By trying different values for  $s$  in Equation 9, they found  $K$  to approach the nearest to constancy when  $s$  was assigned the value 0.0013.

TABLE III. (Luther and Leubner.)

Added hydroquinone $b$ .	Solubility of quinhydrone $a$ (Av.)	$a - b$ .	$K(s = 0.0013)$ .
0.0	0.01827	0.01827	0.221
0.01	0.01421	0.02421	0.227
0.02	0.01150	0.03150	0.236
0.05	0.00664	0.05664	0.227

Luther and Leubner's determinations were repeated in this work and the range extended up to the saturation point for hydroquinone in water, and also in 0.1 molar and molar hydrochloric acid. The results are given in Table IV.

TABLE IV.

On comparing the values obtained in the case of the water solution with those of Luther and Leubner, it will be seen that the values for *a*, the solubility of quinhydrone (dissociated and undissociated), are lower than theirs by about 5%. The reason for this latter difference has not been ascertained. The selected value for *s*, the solubility of the undissociated quinhydrone, which gives the minimum sum of deviations for the dissociation constant, *K*, from its mean, for the range comprising the first four solutions, which was as far as the determinations of Luther and Leubner were carried, is 0.00125 formula-weights per liter, which is a very close agreement with theirs. If, however, the entire range, up to the saturation point of hydroquinone, is considered it will be seen that in the column under *s* = 0.00125, there is a decided but continuous decrease in the value for *K*, until the added hydroquinone amount to *b* = 0.3 mole per liter, and after that a gradual increase occurs which becomes suddenly abrupt at the saturation point of the hydroquinone.

When the smaller values for the solubility of the undissociated quinhydrone, *s*, are considered, it is seen that the first 7 values of the dissociation constant, *K*, in their respective columns become more uniform, giving a minimum deviation sum of 31 for *s* = 0.00098. This latter value for *s* was selected as the solubility, formula weight per liter, in preference to the value, *s* = 0.0013, originally put forth by Luther and Leubner.

Parallel results were obtained with 0.1 and 1 M hydrochloric acid solutions. The calculated solubilities and the dissociation constants for the quinhydrone are recapitulated in Table V. The basis of the last column is given in the subsequent part of the paper.

### Determination of the Hydrogen-Ion Concentration, or the Acidity of the Solutions.

One of the difficulties encountered in this work was the determination of the hydrogen-ion concentration of the various solutions studied. In the case of the acid solutions conductivity data were used for this purpose. This involved, of course, the tentative assumption that the condition of the acid, or hydrogen-ion concentration, was the same as in a pure solution of hydrochloric acid. The question naturally arises, why not determine the hydrogen-ion concentration by the electromotive-force method with a hydrogen electrode. This method was not used at all (although it was realized that the assumption upon which the use of the conductivity values was based, might be the source of considerable error), because it was believed that, even if a constant potential could be obtained with a hydrogen electrode, in the presence of another active electrochemical system this potential still might be very different from the true hydrogen-ion potential because of the influence of the other system. It was felt that this was too big a question to take up in the time at our disposal.

For this reason, the values for the hydrogen-ion concentrations were obtained as follows. Bray and Hunt<sup>11</sup> by the conductivity method, found for the degree of ionization ( $\alpha$ ) of hydrochloric acid at 25°, 92.1% in 0.1*M* solution, and 97.1% in 0.091*M* solution. But no direct data could be found in the literature for 0.1*M* hydrochloric acid at 25°. Kohlrausch,<sup>12</sup> however, gives the following for the equivalent conductivity ( $\Lambda$ ) at 18°:

Moles per liter.	$\Lambda$ .
0.01	370
0.1	351
1.0	301

From these figures  $\Lambda_{.1}/\Lambda_{.01}$  is found to be 0.948 at 18°, while from Bray and Hunt's data  $\alpha_{.1}/\alpha_{.01}$  is found to be 0.948 at 25°. Moreover, according to Kohlrausch,<sup>13</sup> the temperature coefficient of conductivity of

<sup>11</sup> Bray and Hunt, *THIS JOURNAL*, 33, 781 (1911).

<sup>12</sup> Landolt-Börnstein, "Tabellen," 1912, p. 1104.

<sup>13</sup> *Op. cit.* p. 1115.

comparatively constant by saturating the solutions with either hydroquinone or quinone, and with quinhydrone, while the hydrogen ion or acidity varied. The values for the observed potentials of the solutions A, B and C, were obtained by averaging all of the measurements taken on a given mixture during the period in which the readings produced practically a horizontal line. These values are given in Table IX.

Fig. 2.

**Agreement Between the Calculated and Observed Potentials of the solutions, Containing Known Concentrations of Quinone, Hydroquinone and Acid.**—In Table VI is given a comparison between the calculated and observed differences in potentials,  $\pi_1 - \pi_2$ , manifested by different

TABLE VI.

Solution.	$b$ .	$q = a - s$ .	$h = a + b - s$ .	$\pi_1 - \pi_2$	
				Calc.	Obs.
J	0.0	0.01628	0.01628	0.00781	0.0075
I	0.01	0.01208	0.02208		
H	0.02	0.00918	0.02918	0.00741	0.0065
G	0.05	0.00491	0.05491		
F	0.10	0.00261	0.10261	0.0162	0.0155
				0.0163	0.0165

pairs of the solutions, F, G, H, I and J. All of these measurements were done at 25° and in 0.1M hydrochloric acid solutions and therefore Equation 3 above can be written

$$\pi_1 - \pi_2 = 0.0298 \log q_1/h_1 - 0.0298 \log q_2/h_2. \quad (3)$$

The values for  $h$ , the concentration of hydroquinone,  $q$ , the concentration of quinone, in the above solutions, were obtained from the values of  $a$ , the concentration of quinhydrone (dissociated and undissociated) present in the solutions,  $s$ , the concentration of the undissociated quinhydrone, and  $b$ , the amount of added hydroquinone, all of which are given in Table IV. The values of  $b$  are given also in the description of the solutions.

As can be seen in Table VI, the calculated values for the differences in potentials,  $\pi_1 - \pi_2$ , agree quite well with the observed values, and therefore are like those obtained by Haber and Russ. They have, however, the additional weight over the values of Haber and Russ in that they are based on determined concentrations of quinone and hydroquinone instead of assumed values.

**The Solubility of the Undissociated Quinhydrone is Independent of the Presence of an Excess of Hydroquinone.**—It was pointed out in the discussion following Table IV that there is an abrupt increase in the values of the dissociation constant,  $K$ , of the quinhydrone as the solutions become saturated with respect to hydroquinone. Due to the method of trial and Equation 9 used in obtaining the values of  $K$  in Table IV, the assumption was made that the solubility of the quinhydrone,  $s$ , was not affected by the varying concentration of hydroquinone present in the solutions. Some evidence for the justification of this assumption can be had by comparing the potentials of Solutions F to J, which were not saturated with hydroquinone, with the potentials of Solutions A, B and C, which were. It is not extravagant to assume that Solutions A, B and C obey the van't Hoff equation just as Solutions F to J do, since when compared with the latter in this respect (see Table IX below) their potentials appear to be normal.

Solution B has the same acidity as Solutions F to J, and therefore it is possible by means of Equation 3

$$\pi_1 - \pi_2 = 0.0298 \log (q/h)_1 - 0.0298 \log (q/h)_2 \quad (3)$$

to obtain an expression involving only the one unknown  $(q/h)_2$ , since  $(q/h)_1$  is given in Table VI and the potentials,  $\pi$ , can be obtained from the graphs. Inspection of Fig. 1 shows that Solution F gives a very stable potential. Therefore the data for this solution were selected as the basis of this calculation, taking for  $\pi_F$ , the initial reading, 0.8695 volt, obtained as explained above, and which is also the average of the readings up to the point at which the falling off commences. Similarly Solution B, Fig. 2, has an average value for  $\pi_B$  of 0.8300 volt. Introducing these values and also  $-0.0475$  for  $0.0298 \log (q/h)_F$ , from Table VI, in Equation 3

$$0.8695 - 0.8300 = -0.0475 - 0.0298 \log (q/h)_B \text{ or } (q/h)_B = 0.001202.$$

But  $h_B$ , the concentration of hydroquinone in 0.1M hydrochloric acid

is 0.633 mole per liter (Table I) and therefore  $q_B$ , the concentration of the quinone in Solution B is 0.00076 mole.

Since Solution B was saturated with hydroquinone and quinhydrone, the total quinhydrone (dissociated and undissociated), present in the solution, and  $a_B$  is 0.00181 mole (Table IV), is equal to the undissociated quinhydrone  $s_B$  plus the concentration of the free quinone  $q_B$  is 0.00076 mole, because the number of moles of the latter is equivalent to that of the dissociated quinhydrone in this case since no quinone had been added to the solution. Then from

$$a_B = s_B + q_B \dots \dots \dots (6)$$

the solubility  $s_B$  of the undissociated quinhydrone in Solution B is 0.00105 mole per liter. This value is so close to 0.00102, the value assumed in Table IV, that the assumption mentioned above appears to be justified.

Instead of using Solution F for this purpose, the other solutions, G, H, I and J, were tried also and gave the following results:

Basis.	$s_B$ .
F	0.00105
G	0.00105
H	0.00101
I	0.00094
J	0.00092

The values obtained when Solutions I and J were used as the basis for the calculations of the concentration of the undissociated quinhydrone,  $s_B$ , are slightly lower. The higher values from Solutions F, G and H are to be preferred because these solutions manifested more stable and definite potentials, as is evident from our examination of the corresponding curves, especially those of F and G in Figs. 1 and 2.

**Calculation of Potentials of Solutions, Saturated with Hydroquinone and of Various Acidities.**—Adopting, for the reasons just stated above the values for  $s$ , the solubility of the undissociated quinhydrone showing the smallest deviation from the mean, and given in Table IV, it becomes possible to calculate the potentials of Solutions A, B and C. The procedure followed in these calculations differs from that in the case of Solutions F to J, in that the acidity of the solutions varied and therefore had to be taken into account in Equation 3, or

$$\pi_1 - \pi_2 = 0.0298 \log(q/h)_1 + 0.0596 \log[H^+]_1 - 0.0298 \log(q/h)_2 - 0.0596 \log H^+_2 \quad (10)$$

The values of the hydrogen-ion concentrations are given in the section dealing with the concentration of hydrogen ion. The values of  $q$ , the concentration of the free quinone, are obtained by means of Equation 6, and since the solutions were saturated with respect to hydroquinone, the value of  $h$  is given in Table I. The values for  $a$ , the total concentration

of quinhydrone (dissociated and undissociated) and  $s$ , the concentration of the undissociated quinhydrone, are given in Table IV. The value of  $s$  for Solution C, which was 0.001  $M$  with respect to hydrochloric acid, is considered to be the same as that for pure water. No solubility experiments for 0.01  $M$  hydrochloric acid solutions were run because the results obtained for 0.1  $M$  hydrochloric acid and water were so nearly the same that these determinations for 0.01  $M$  hydrochloric acid seemed unnecessary. The results obtained are given in Table VII.

TABLE VII.

Solution.	$\frac{q}{a-s}$	$h$	$H^+$	$\pi_1 - \pi_2$ Calc.	$\pi$ Obs.	$\pi_1 - \pi_2$ Obs.
A	0.00072	0.494	0.790	0.0579	0.883	0.053
B	0.00079	0.633	0.0921		0.830	
C	0.000835	0.645	0.00971	0.0576	0.770	0.060

In like manner,  $\pi_A - \pi_C = 0.1155$  (calc.) and 0.113 (observed). Thus the observed potentials are found to agree quite well with the theoretical, just as was found to be the case for Solutions F to J, even though in these solutions the concentration of the hydrogen ion was varied.

**The Equilibrium Constant of the Oxidation-Reduction Reaction between Quinone and Hydroquinone.**—The value of the equilibrium constant, for the oxidation-reduction reaction (1) between quinone and hydroquinone,  $K$ , was obtained by means of Equation 2.

$$\pi = 0.0298 \log(q/h) + 0.0596 \log[H^+] - 0.0298 \log K \dots \dots (2)$$

The concentrations of the free quinone and hydroquinone,  $q$  and  $h$ , were taken from Tables VI and VII. The hydrogen-ion concentration can be found in the section dealing with the concentration of hydrogen ion. In Table VIII are given the values for  $K$ , obtained in the form  $0.0298 \log K$ .

TABLE VIII.

Solution.	A.	B.	C.	F.	G.	H.	I.	J.
$-0.0596 \log H^+$	0.0061	0.0618	0.1200	0.0618	0.0618	0.0618	0.0618	0.0618
$\pi$	0.8830	0.8300	0.7700	0.8695	0.8860	0.9015	0.9075	0.9150
$-0.0298 \log(qh)$	0.0845	0.0867	0.0861	0.0475	0.0312	0.0149	0.0078	0.0000
$0.0298 \log K$	-0.9736	0.9785	0.9761	0.9788	0.9790	0.9782	0.9771	0.9768
Deviation	-0.0037	+0.0012	-0.0012	+0.0015	+0.0017	+0.0009	-0.0002	-0.0005

The mean value for  $0.0298 \log K$  is 0.9773, and hence the equilibrium constant for Reaction 1 is  $K = 1.6 \times 10^{-23}$ .

The average deviation in the values for  $0.0298 \log K$ , as can be seen in Table VIII, is 0.0014 volt or 1.4 millivolts. This compares favorably with the closest agreement that has been obtained in parallel work in inorganic chemistry, as can be seen from the following summary.

System.	Investigators.	Average dev. millivolts.
Ferrous/ferric	Peters(Tab. 1)	3.9

Hydroquinone/quinone	This work	1.4

### Comparison of the Theoretical and Observed Potentials.

By using the mean value, obtained above for  $0.0298 \log K = 0.9773$  the theoretical values for the potentials of the various solutions have been calculated and arranged together with the observed values in Table IX for the sake of comparison.

TABLE IX.

Solution	$\pi$ (Calculated).	$\pi$ (Observed).
A	0.8867	0.8830
B	0.8288	0.8300
C	0.7712	0.7700
F	0.8680	0.8695
G	0.8843	0.8860
H	0.9006	0.9015
I	0.9077	0.9075
J	0.9155	0.9150

The theoretical potentials are represented in the figures by the straight dotted lines.

**Potential Measurements on Unstable Solutions.**—Seven cells saturated with quinone and a great number of neutral and alkaline solutions, in which potassium chloride and sodium hydroxide were used as electrolytes, were run also. Full details on these measurements are given in the original dissertation.<sup>14</sup> They are omitted here, for the reason that on account of the extreme instability of these solutions they could not be made the basis of any quantitative calculations.

Qualitatively, however, they were perfectly in accord with the theory. The solutions saturated with quinone, as already shown, gave higher oxidizing potentials than solutions of the same acidity, but of lower ratio between the quinone and the hydroquinone,  $q/h$ . The neutral solutions gave lower potentials than the acid solutions, and the alkaline gave still lower potentials, decreasing as the alkalinity was increased.

<sup>14</sup> "Oxidation and Reduction in Organic Chemistry from the Standpoint of Potential Differences," by F. S. Granger. Columbia University Press, New York, N. Y., 1920.

### Experimental Part.

**Hydroquinone.**—The hydroquinone used was partly Merck's and partly Eimer and Amend's. Only one grade was obtainable and it was claimed to be very pure. No accurate method for determining its purity could be found. It all melted at  $169^{\circ}$  (uncorrected), the same value as given by Hlasiwetz,<sup>15</sup> or  $173.0^{\circ}$  (corrected). The solubility determinations of the hydroquinone were made by evaporating 5 cc. of a saturated solution to constant weight in weighed flasks, at room temperature and about 25 mm. pressure.

**Quinone.**—The quinone was Kahlbaum's. Some of it was recrystallized from gasoline (which was found to be an excellent solvent for this purpose). Both methods gave clean, bright yellow products, titrating, by the method already described, 99.4% of the theoretical requirement, and melting sharply at  $115.7^{\circ}$  (corrected), the melting point given in Beilstein.

**Quinhydrone.**—The quinhydrone was prepared in two ways: by treating an aqueous solution of hydroquinone with ferric chloride, and then acidifying with hydrochloric acid; and by mixing equivalent amounts of hydroquinone and quinone in water. The product, in each case, was filtered off and washed with water. That by the first process titrated 99.2% of the theoretical amount by the method previously described. Some was recrystallized from alcohol followed by ether, and some from glacial acetic acid. Acetic acid proved to be a very good solvent for the purpose, being by far the best of the three. All of the recrystallized products titrated 99.4%. Only the samples giving this titration were used. Quinhydrone decomposes upon heating, so its purity can not be checked in this way.

In determining the solubility of the quinhydrone, solutions containing an excess of the material were placed in a large test-tube fitted with a spiral mechanical stirrer, immersed in the thermostat, and vigorously and continuously stirred. Samples were taken out every 15 to 30 minutes, by means of a pipet fitted with a filter, until two successive titrations gave the same value, which was usually the case with the first two samples. In a number of cases, fresh mixtures were made up and tested as checks, and all the results were almost identical with the original, so it was not deemed necessary to verify all the solutions in this way, the regularity of the results and the parallelism between the aqueous and acid solutions also serving as a check.

**Potential Measurements.**—Sensitive Leeds and Northrup potentiometer and galvanometer were used. Saturated potassium chloride solution was used as the connecting medium. The cells were kept immersed in a constant temperature bath at  $25^{\circ}$ , the temperature remaining constant to  $0.01^{\circ}$ . Nitrogen was bubbled through the solution in the cell, for the first few hours, to insure complete removal of the air and to provide agitation at the start. The gas inlet and outlet tubes were closed then to prevent access of air. The potential of each cell was measured at least once a day over a period of from one to three weeks. Two or more cells of each solution were made up and examined, usually at different times and sometimes with different lots of materials, in order to determine the reproducibility of the potentials measured. No marked difference was observed, whether the electrodes were platinized or not.

The authors wish to express their appreciation to the Harriman Research Laboratory for aid in this investigation.

THE FACTORS AFFECTING THE STABILITY OF ADDITION COMPOUNDS IN SOLUTION AND THEIR INFLUENCE UPON IONIZATION EQUILIBRIA (Part I).<sup>1</sup>

BY JAMES KENDALL AND PAUL M. GROSS.

Received January 11, 1921.

It is unfortunate that any attempt to modify the currently accepted ionization theory inevitably introduces a great many complicating factors, especially when solutions of finite concentration are considered. Compound formation between solvent and solute, changes in molecular complexity of solvent and solute, complex ion formation, etc.—all these are influences about which so little is definitely known that it soon becomes impossible to treat the subject satisfactorily in a strictly quantitative manner. Before any real advances can be made toward a new and more comprehensive theory it will consequently be necessary to examine very closely the effect of these various factors upon the simple equilibrium postulated at present between “ionized” and “non-ionized” solute.

Some preliminary steps in this direction have been made in earlier

<sup>1</sup> This article was practically completed in 1917 (see Kendall, Booge and Andrews, *THIS JOURNAL*, 39, 2303 (1917)); its publication has been delayed by the absence of both authors on war work and by the subsequent postponement of the additional experimental tests which it was desired to impose upon the views here put forward. The first section of this confirmatory experimental work is now presented in the succeeding article.

In the interim, many investigators in this field have followed Milner, (*Phil. Mag.*, 35, 214 and 354 (1918)) and Ghosh (*J. Chem. Soc.*, 113, 449 and 627 (1918)) in postulating complete ionization in solutions of strong electrolytes. Mention may be made in particular of recent articles by A. A. Noyes and MacInnes (*THIS JOURNAL*, 42, 239 (1920)), and by Langmuir (*ibid.*, 42, 287 (1920)). The whole question of the abnormality of strong electrolytes, as related to the ionization hypothesis advanced in this and previous papers, will be dealt with in detail in a subsequent article of this series, so that it would be premature to dwell upon the matter at this point. As may be gathered from the contents of this communication, however, the present authors are not in agreement with the fundamental assumption of Ghosh that the *only* equilibrium to be considered in a solution of a strong electrolyte  $RX$  in water is the electrostatic equilibrium between simple “free” and “bound” ions  $R^+$  and  $X^-$ , but insist upon the additional necessity of taking into account the existence of solvent-solute complexes in all conducting solutions and their influence upon ionization. Inter-ionic attractive forces must undoubtedly be recognized in any final quantitative treatment of the problem, but no satisfactory solution can possibly be obtained if all other factors are totally neglected. In this connection it may be profitable to repeat the opinion clearly expressed in a recent paper by Wells and Smith (*THIS JOURNAL*, 42, 185 (1920); see also previous articles by G. McP. Smith in *ibid.*) that our failure to elucidate ionization equilibria has been mainly due to our refusal to take into account the occurrence of complex chemical reactions between the different ionic and molecular species in the solution. The factors affecting such reactions are further discussed in the present communication.

articles of this series.<sup>2</sup> The basis of the hypothesis there advanced is that ionization in solution is preceded by the formation of solvent-solute complexes, and that the disintegration of these into ions of opposite charge results from the diminished electrostatic attraction between the constituent radicals. The extent of ionization in any solution will consequently depend upon (a) the extent of compound formation; *i. e.*, the degree to which reactions of the type  $AB + CD \rightleftharpoons AB \cdot CD$ <sup>3</sup> proceed from left to right in a mixture of AB and CD in the liquid state; and (b) the extent of the dissociation of these compounds into ions of opposite charge; *i. e.*, the degree to which reactions of the type  $AB \cdot CD \rightleftharpoons A^+ + (B \cdot CD)^-$  proceed from left to right in the same mixture.

If the amount of compound formation is large and if these compounds are, ionically, extremely unstable, then the solution will exhibit a high conductivity. On the other hand, where there is little combination or where the compounds formed are comparatively stable ionically, the conductivity of the mixture can be but small.

We shall therefore be able to *predict* the extent of ionization in any solution when we have once established what factors affect the formation and the ionic stability of solvent-solute complexes in general. The first half of this problem has already been discussed,<sup>4</sup> and it has been demonstrated experimentally that the extent of formation of addition compounds between solvent and solute (in other words the stability of complexes *with respect to their components*) increases uniformly with the differences in character (*i. e.*, in the positive or negative nature of the constituent groups) of these components. It is particularly noteworthy that complexes other than the simplest possible type  $AB \cdot CD$  are formed in quantity only when AB and CD are decidedly diverse.

In the present article the study of the second half of the problem—the factors affecting the stability of solvent-solute complexes *with respect to their ionic dissociation products*—is initiated. In their simplest form<sup>5</sup>

<sup>2</sup> Kendall, Booge and Andrews, *THIS JOURNAL*, 39, 2303 (1917); Kendall and Booge, *ibid.*, 39, 2323 (1917). These articles also give references to the extensive work of previous investigators upon various aspects of the problem. Two typographical errors in the equations given in the former paper may be corrected here. On p. 2309, read  $1/T_0$  instead of  $T_0$  in Equation 2. On p. 2313, read 1200 *c* instead of 12000 calories in the equation on line 9.

<sup>3</sup> In the first articles of this series (*e. g.*, Kendall, *THIS JOURNAL*, 36, 1242 (1914)) the mechanism of this type of reaction was discussed in a very inadequate manner, an ionic basis being postulated. However, as has been pointed out by Dehn (*ibid.*, 39, 2647 (1917)), a reaction is not necessarily ionic because it is instantaneous. A more logical view has been briefly outlined in a later article (Kendall and Booge, *ibid.*, 39, 2328 (1917)), and in favor of this view the earlier argument may now be definitely discarded.

<sup>4</sup> For a résumé see Kendall, Booge and Andrews, *loc. cit.*, p. 2304.

<sup>5</sup> The arguments which follow immediately below are independent of the actual formula of the complex or of its mode of ionization.

the reactions here involved may be written,  $AB \cdot CD \rightleftharpoons A^+ + (B \cdot CD)^-$ . The case where AB and CD are identical molecules (or  $AB \cdot CD$  is an associated pure liquid) may first be briefly considered.

### The Ionization of Pure Liquids.

Any liquid, the simple molecules of which contain unsaturated atoms, will exhibit to a greater or less degree the phenomenon of association.<sup>6</sup> As a consequence of this association, the moments of the electrical doublets present in the simple molecules are considerably increased, and the constraints upon the electrons correspondingly diminished. The higher the degree of association, therefore, the less firmly are the constituent groups of the complex molecules held together, and the more readily will disintegration into ions of opposite charge take place. We should expect, then, that self ionization is in general a property *characteristic of highly associated liquids*. In a series of liquids of similar type, arranged in order of ascending molecular complexity, a regular increase in specific conductivity should be apparent.<sup>7</sup>

Such is in fact the case. Ideal non-associated liquids (such as the saturated hydrocarbons) possess practically zero conductivity.<sup>8</sup> Other normal organic substances (for example, benzene, chloroform, ether) are extremely poor conductors, the specific conductivity at 25° being of the order  $10^{-4}$ . When we examine the associated organic liquids,<sup>9</sup> somewhat higher values are recorded in the literature: *e. g.*, formamide,  $\kappa_{25^\circ} = 4.7 \times 10^{-5}$ ; acetone,  $\kappa_{25^\circ} = 2.27 \times 10^{-7}$ ; formic acid,  $\kappa_{25^\circ} = 6 \times 10^{-6}$ ; methyl alcohol,  $\kappa_{25^\circ} = 1.45 \times 10^{-6}$ . Even water, however, with an association factor probably between 2 and 3 at ordinary temperatures, has very little conductivity when perfectly pure;  $\kappa_{25^\circ} = 0.55 \times 10^{-7}$ .

It is only when we come to consider fused salts,<sup>10</sup> where the apparent molecular complexity may be as high as 8 to 10, that we find examples of "pure" substances highly dissociated into ions. The following table<sup>11</sup> indicates clearly how specific conductivity varies with association in a

<sup>6</sup> See Kendall and Booge, *loc. cit.*, p. 2327.

<sup>7</sup> The effect of other factors, which will be considered later, must however be borne in mind in the application of this rule. The viscosity of each liquid is a property to be taken into account in any comparison. (See particularly Walden, *Z. physik. Chem.*, **55**, 246 (1906)).

<sup>8</sup> Scudder, "Conductivity and Ionization Constants of Organic Compounds," D. van Nostrand Co., 1914.

<sup>9</sup> Walden, *Z. physik. Chem.*, **46**, 103 (1903). It is probable that the presence of small traces of difficultly removable impurities renders the values given in most cases considerably too high. See Schlesinger and Martin, *THIS JOURNAL*, **36**, 1592 (1914); also the experimental section of the succeeding article.

Specific conductivity in a pure liquid, therefore, is primarily dependent upon the association factor. To go further we must ask the question: upon what does the degree of association of a pure liquid depend? Examination of the available data shows that here, *just as in two component systems*, the formation of complexes is conditioned primarily by the differences in character (*i. e.*, in the positive or negative nature) of the several groups concerned. Thus in a substance where we have a highly electro-positive and a highly electronegative conjunction, ideal opportunity is afforded for the production of highly associated molecules.<sup>14</sup> When differences in character are less pronounced, less association occurs. We can, indeed, trace a general trend towards increasing or decreasing molecular complexity (so far as our elementary knowledge of association factors allows) as we proceed through any particular series of compounds

<sup>12</sup> The term "*associated*" is hardly adequate to express the condition of fused salts such as NaCl and KCl, the term *polar* being far more pertinent (compare Hildebrand, *THIS JOURNAL*, 38, 1463 (1916)). The fact that the electron has already passed between the atoms has been regarded by most recent investigators, indeed, as establishing that such substances are not associated at all, but completely ionized. The transfer of an electron, however, does not necessitate the independence of the radicals involved, and the use of the term *completely ionized* to include both *free* and *bound* ions is liable to lead to serious confusion of ideas (compare Harkins, *Proc. Nat. Acad. Sci.*, 6, 601 (1920)). Neither *ionized* nor *associated* alone gives a true representation of the state of affairs in a fused salt such as NaCl; the physicist may center his attention upon the passage of the electron and the lack of a definite bond between any two particular ions, while the chemist may lay more stress upon the forces exercised by any one radical upon all oppositely-charged radicals surrounding it and, the consequent "pooling of affinity." The two views are not exclusive but supplementary.

<sup>13</sup> The association factors given are the mean of those obtained by the surface tension method of Ramsay and Shields (*J. Chem. Soc.*, 63, 1099 (1893)) and by the specific cohesion equation of Walden (*Z. physik. Chem.*, 65, 129 (1909)). Other methods of estimating association give here, in several instances, very divergent results (see Walden, *Z. Elektrochem.*, 14, 723 (1908)).

<sup>14</sup> See Kendall and Booge, *loc. cit.*, pp. 2327-8.

arranged in order of the electro-affinity of the variable radical. Thus hydrogen fluoride is highly associated even in the gaseous state and at ordinary temperatures, hydrogen chloride is highly associated only when liquefied, while hydrogen bromide and iodide are only slightly associated even as liquids at low temperatures.<sup>15</sup> In the same way, comparing analogous compounds of succeeding elements in the periodic system, we have "association factors" as follows:  $\text{NaCl} > \text{MgCl}_2 > \text{AlCl}_3 > \text{SiCl}_4$ ; and also,  $\text{CH}_4 < \text{NH}_3 < \text{H}_2\text{O} < \text{HF}$ . Other illustrative examples will readily suggest themselves.<sup>16</sup>

### Ionization in Solutions.

From what has already been said it will be evident that a mixture of two ideal saturated substances (*e. g.*, two hydrocarbons) cannot give a conducting solution, also that the specific conductivity of a solution of an unsaturated substance in a saturated liquid (*e. g.*, hydrogen chloride in a hydrocarbon) will be, in general, exceedingly small.<sup>17</sup>

A mixture of two unsaturated substances, however, affords several possibilities. The results of actual experiment may be separated into three types. In the first, the specific conductivity of the mixture is not widely different from that of its components (usually very small); in the second, the conductivity is markedly greater, but still not exceptionally high; in the third, the conductivity is very great, even if the mixture is formed from two practically non-conducting substances.

The first case is typical of all mixtures in which the two components are similar in character (*i. e.*, for acids and bases, where the acidic or basic strengths are of the same order). Here there will be little or no increase in molecular complexity through compound formation on admixture; the chief effect rather will be mutual dissociation of any complex molecules of the pure components.<sup>18</sup> Hence the conductivity of the solution will not differ greatly from that of its original constituents, and (except in the case of mixtures of fused salts) will always be small. As examples may be cited

<sup>15</sup> See Turner, *J. Chem. Soc.*, 99, 890 (1911).

<sup>16</sup> For full references on this topic see the monograph "Molecular Association," by Turner, (Longmans, Green and Company, 1915).

<sup>17</sup> In any case it will be *less* than that of the unsaturated component when pure, since the degree of association of this component (hence also its tendency towards ionization) will be diminished with the decrease in its concentration.

<sup>18</sup> An apparent exception is the case where both substances are highly associated (*e. g.*, in such a system as phenol: cresol), when compounds of the general type  $(\text{AB})_x$ .  $(\text{CD})_y$  are undoubtedly formed (see Dawson and Mountford, *J. Chem. Soc.*, 113, 923 (1918)). The *average* molecular complexity of such a mixture, however, (and hence its specific conductivity also) will not differ greatly from that of its pure components, since extensive disassociation of these is also involved. The complexes here existent are to be regarded, indeed, not as *substitution* but as *substitution* compounds, as will be shown in detail in a subsequent article.

(a) two very weak electrolytes, water and methyl alcohol;<sup>19</sup> (b) two very strong electrolytes, trichloro-acetic acid in hydrogen bromide.<sup>20</sup> Numerous other instances may be found by reference to Scudder's "Conductivity and Ionization Constants of Organic Substances."

As the characters of the two substances begin to diverge, the extent of compound formation between them will become appreciable. Unless the divergence is very marked, however, the formation of complexes will be limited to the simplest type, and the degree of dissociation of this into its components in the liquid state will be considerable. In other words, the addition of AB to CD involves the production of only a small amount of a new molecular species AB.CD, the least complex (and consequently possessing the least tendency towards ionic disintegration) of all possible compounds. While, therefore, the conductivity of the solution may considerably exceed that of its components, it will still not be especially high. As examples may be given any weak acid or base in water, and hydrogen chloride in formic acid.<sup>21</sup>

If the two substances are decidedly diverse, extensive compound formation will occur on admixture. The complexes formed will include not only the simple type AB.CD but also other and larger molecular species of the general formula  $(AB)_x.(CD)_y$ . Disintegration of these complexes into ions of opposite charge, taking place very readily, will render the solution an exceedingly good conductor. As examples may be given any strong acid or base in water, and methyl alcohol in hydrogen chloride.<sup>22</sup>

The essential features of a solution of high specific conductivity are, therefore: (a) unsaturation in both components; (b) a decided difference in the character of the two components. The first is necessary to enable compound formation to occur at all, the latter is the "driving force" which regulates the increase in molecular complexity (and hence in ionization) on admixture. The following additional examples will illustrate the uniform gradations experimentally observable as these factors are separately varied: (a) *unsaturation*; hydrogen chloride in octane is a non-conductor, in benzene an exceedingly poor conductor, in ether a fair conductor, in alcohol a good conductor, in water an excellent conductor; (b) *diversity*; in liquefied hydrogen chloride<sup>20</sup> as solvent, acetic acid is a good conductor, formic acid not so good, chloro-acetic and cyano-acetic acids poor conductors, trichloro-acetic acid a non-conductor. The conductivity decreases regularly as the acidic strength of the solute approaches that of the solvent. Similarly Walden,<sup>23</sup> considering the

<sup>23</sup> Walden, *Trans. Faraday Soc.*, 6, 71 (1910).

conductivity of solutions with water as solute, found that water in liquid hydrogen cyanide is a poor conductor, in formic acid a fair conductor, in sulfuric acid a good conductor.

The examples cited in the foregoing paragraphs furnish valuable cumulative evidence for the presumable validity of the principles underlying the ionization hypothesis here advanced. It must be freely conceded, however, that the greater part of previously recorded work on specific conductivity in non-aqueous solutions has been of a very rough order of accuracy, and it seems scarcely justifiable to base such important generalizations entirely upon isolated measurements of this nature. Consequently, in order to test more systematically the general applicability of the rules regarding ionization outlined above, exact conductivity determinations have been carefully carried out upon several series of typical two-component systems, for each of which the relative extent of compound formation in the liquid state had already been established in earlier articles.

As will be seen by reference to the paper immediately following, the experimental results obtained are in complete accordance with the theory developed, since compound formation and ionization (as given *qualitatively* by specific conductivity)<sup>24</sup> proceed uniformly in parallel throughout each of the systems studied. Where the extent of compound formation is known to be minute, the conductivity is almost immeasurable; as compound formation increases in amount, the conductivity becomes appreciable; where combination is extensive, the conductivity is very markedly increased. A fundamental relationship between the two phenomena is therefore confirmed.

In a later article other factors affecting the formation and stability of addition compounds in solution (such as the influence of ionic volume, of valence, and of temperature) will be discussed. Although these factors are subsidiary to the "diversity factor" here examined, occasional minor divergences from the general rules may be referred to their effect, as will be shown by the consideration of some typical examples.

In conclusion here, it is of importance to indicate how far the above views can be correlated with those expressed by previous investigators in the same field. Owing to the scope of the subject, it is not possible to consider all sides of the question in detail, consequently the discussion will, for space considerations, be limited to two most significant topics—Abegg and Bodländer's theory of complex ions, and Werner's theory of bases and acids. Many other workers have dealt equally intimately and ex-

<sup>24</sup> Specific conductivity is not in itself, of course, an exact measure of the extent of ionization in a solution; other factors (*e. g.*, viscosity, ionic mobility, molecular volume) must also be considered. The corrections introduced by the consideration of these factors will be the subject of a later paper.

tensively with other aspects of the connection between compound formation and ionization in solutions, but reference to their researches must be made directly by the reader.<sup>25</sup>

### The Theory of Complex Ions.

It has been shown in the preceding pages that, in binary solutions, increasing compound formation is regularly accompanied by increasing ionic instability; "union with another molecule promotes ionization." Suppose now that to a binary solution in which there is but little tendency towards ionization we add a third substance which combines very extensively with one of the original components. Obviously the same reasoning will still apply, the increase in molecular complexity will result in increased ionization.

This is Abegg and Bodländer's well-known theory of electro-affinity<sup>26</sup> (which has more recently been restated by Lewis,<sup>27</sup> Hildebrand<sup>28</sup> and Harkins),<sup>29</sup> arrived at from a new angle. Indeed, the whole theory of ionization outlined in this article may be considered, in one sense, as an extension of Abegg and Bodländer's generalizations regarding complex ions to solutions in general.<sup>30</sup> While in a simple substance AB the attractive forces between the constituent radicals usually suffice to inhibit marked ionization, the formation of complexes on addition of a second substance CD will weaken these attractive forces and disintegration of the complex molecules into oppositely charged ions will much more readily occur. Similarly for solutions; a "weak electrolyte" in any given solvent becomes a "stronger electrolyte" by combination with a second solute.<sup>31</sup> As illustrations the following systems may be cited; additional examples are to be found in the article immediately succeeding.

ORIGINAL SYSTEM ("WEAK ELECTROLYTE").	ADDED SUBSTANCE.	RESULTANT COMPOUNDS ("STRONGER ELECTROLYTES").
H <sub>2</sub> O or SO <sub>3</sub>	SO <sub>3</sub> or H <sub>2</sub> O	H <sub>2</sub> SO <sub>4</sub> ; H <sub>2</sub> S <sub>2</sub> O <sub>7</sub> ; H <sub>2</sub> SO <sub>4</sub> ·xH <sub>2</sub> O
NH <sub>3</sub> or H <sub>2</sub> O	H <sub>2</sub> O or NH <sub>3</sub>	NH <sub>4</sub> OH
(C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub> O or HCl <sup>32</sup>	HCl or (C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub> O	(C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub> O·HCl; (C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub> O·2HCl; (C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub> O·5HCl.

<sup>25</sup> A representative list of references will be found in an earlier article (Kendall and Booge, *THIS JOURNAL*, 39, 2324 (1917)). See also Senter, *Trans. Faraday Soc.*, 15, 4 (1919).

<sup>26</sup> Abegg and Bodländer, *Z. anorg. Chem.*, 20, 453 (1899); 39, 330 (1904).

<sup>27</sup> G. N. Lewis, *THIS JOURNAL*, 38, 762 (1916).

<sup>28</sup> Hildebrand, *ibid.*, 38, 1464 (1916).

<sup>29</sup> Harkins and Hall, *ibid.*, 38, 216 (1916); Harkins and King, *ibid.*, 41, 970 (1919).

<sup>30</sup> The main points of advance are the inclusion of non-aqueous solutions and the insistence upon the equality of solvent and solute in ionization phenomena.

<sup>31</sup> Compare the less definite statement of Lewis (*loc. cit.*): "A slightly polar molecule becomes more strongly polar in the presence of another polar molecular type."

<sup>32</sup> Maass and McIntosh, *THIS JOURNAL*, 35, 538 (1913).

ORIGINAL SYSTEM ("WEAK ELECTROLYTE").	ADDED SUBSTANCE.	RESULTANT COMPOUNDS ("STRONGER ELECTROLYTES").
HCN in H <sub>2</sub> O	Fe(CN) <sub>2</sub>	H <sub>4</sub> Fe(CN) <sub>6</sub>
H <sub>2</sub> CrO <sub>4</sub> in H <sub>2</sub> O	CrO <sub>3</sub>	H <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub>
dimethylpyrone in organic solvents <sup>33</sup>	CCl <sub>3</sub> .COOH	C <sub>7</sub> H <sub>8</sub> O <sub>2</sub> .CCl <sub>3</sub> .COOH; C <sub>7</sub> H <sub>8</sub> O <sub>2</sub> .2CCl <sub>3</sub> .COOH.

Ionization is thus, essentially, a consequence of compound formation. In certain molecular types, of course, instability may be so extreme that ionic disintegration is appreciable even in the simple molecule (*e. g.*, in the case of liquid iodine;<sup>34</sup>  $I_2 \rightleftharpoons I^+ + I^-$ ). In others, conversely, stability may be so great that ionization is still inappreciable even although the molecule is exceedingly complex (*e. g.*, organic substances in general, although even here the ionic instability of "over-loaded" molecules such as hexaphenylethane<sup>35</sup> may be noted). In solutions in general, however, there is no difficulty in tracing a clear-cut parallelism between increase in molecular complexity and increase in "ionic instability."<sup>36</sup> The analogy of the increasing instability of the atom itself with increasing complexity<sup>37</sup> (*i. e.*, the disintegration of radio-active elements of high atomic weight) is not without interest.

### Werner's Theory of Bases and Acids.

The particular case of aqueous solutions only will be considered here. A fundamental distinction is drawn by Werner between "anhydro-" and "aquo-" bases and acids.<sup>38</sup> "Anhydro-" bases and acids (*e. g.*, NH<sub>4</sub> OH; HCl) are not compounds which dissociate directly, but are compounds from which, *by the addition of water*, the true (or "aquo") bases and acids are produced. Thus, for an acid HX, the following ionization mechanism is postulated,

or

The hydrogen ion in the aqueous solution of such an acid is therefore not produced by the dissociation of the acid, but rather comes directly from the water. Bases and salts are similarly treated, and the conclusion drawn that water plays the chief part in ionization.

<sup>33</sup> Plotnikow, *Ber.*, 39, 1794 (1906); compare Walden, *ibid.*, 34, 4194 (1901); McIntosh, *THIS JOURNAL*, 32, 542 (1910).

<sup>34</sup> Abegg, "Handbuch der anorg. Chem.," [2] 4, 256 (1913).

<sup>35</sup> Gomberg, *THIS JOURNAL*, 36, 1144 (1914).

<sup>36</sup> Thus in all three cases in the table above where more than one complex is formed, the most simple is the most stable; the equimolecular compound exhibits the smallest conductivity.

<sup>37</sup> Subsidiary factors, such as atomic volume, valence, etc., will also induce minor irregularities in this general rule (see p. 1422).

<sup>38</sup> Werner, "New Ideas on Inorganic Chemistry," 1911, pp. 200-219.

While this interpretation is, at first sight, in full accordance with the theory outlined in the present paper, yet on closer examination an important point of difference appears. It is certainly possible to consider water as the *ionizing* substance in all conducting aqueous solutions and to derive thereby a theory of solutions just as satisfactory, in every respect, as that given by the more popular procedure of treating water as merely an inert "medium" for the ionized solute.<sup>39</sup> Either extreme becomes equally illogical, however, as soon as we accept the essential and absolute equality of the two components in a conducting solution.

Ionization in a system  $RX-H_2O$  is, under such a view, regarded as resulting from the disintegration of complexes of the general type  $(RX)_m \cdot (H_2O)_n$ .<sup>40</sup> Cleavage is, of course, *possible* at any point in the complex molecule, and a large number of distinct ionic types may be obtained, the relative concentrations of which will vary with the composition of the solution. There is no *a priori* reason either for the assertion of the ionists that the cleavage necessarily occurs in the  $RX$  molecule, or for Werner's claim that dissociation is restricted to the water molecule. In the great majority of conducting solutions, probably, both species of dissociation take place to extents which cannot be neglected, and consequently the simple equation  $RX \rightleftharpoons R^+ + X^-$  totally fails to reproduce the ionization equilibria. In extreme cases, indeed, such as a "strong electrolyte" in water, the total number of complex molecular and ionic types present must be very large, and since all complex molecules will be, ionically, more unstable than the simple salt, it is evidently quite incorrect to consider the experimental "ionization values" (as ordinarily determined) as representing the actual concentration of the simple ions  $R^+$  and  $X^-$ . Further discussion of this topic must, however, be left for a future communication.

### Summary.

In a preceding article, the formation of solvent-solute complexes has been postulated as a prerequisite to ionization in solutions. Under this assumption, we should be able to predict the degree of dissociation in any given solution from (a) the stability of the complexes with respect to their components, and (b) the instability of the complexes with respect to their ionization products.

The first of these points has been dealt with in detail in previous papers, and the rules formulated have here been extended to the association of

<sup>39</sup> See Kendall and Booge, *THIS JOURNAL*, 39, 2333 (1917).

<sup>40</sup> The structural formula of such complexes and the mechanism of compound formation and ionic disintegration, especially as related to the Lewis-Langmuir theory of valence (Langmuir, *THIS JOURNAL*, 42, 276 (1920)), will be discussed in detail later. For the present, reference should be made to a few preliminary remarks in an earlier article (Kendall and Booge, *ibid.*, 39, 2327 (1917)).

pure liquids. In the present communication the study of the second point—the factors affecting the ionic disintegration of solvent-solute complexes in solution—has been started, and additional generalizations<sup>41</sup> deduced. These generalizations have been shown to be in excellent qualitative agreement with the experimental data of earlier investigators. A more stringent test of their validity has been successfully sought by careful conductivity determinations on specially selected systems, as described in the article immediately succeeding.

The connection between the ionization hypothesis here presented and the views of Abegg and Bodländer on the one hand, and of Werner on the other, has been briefly examined and some points of difference indicated.

In a future article the factors affecting the formation and stability of addition compounds in solution will be further discussed, and the problem of strong electrolytes investigated.

## COMPOUND FORMATION AND SPECIFIC CONDUCTIVITY IN SOLUTIONS OF THE TYPES ACID:ESTER, ACID:KETONE AND ACID:ACID.

BY JAMES KENDALL AND PAUL M. GROSS.

Received January 11, 1921.

As explained in the preceding article,<sup>1</sup> the purpose of this investigation is to test, more stringently than can be done by existent data, the general validity of the hypothesis that ionization in solutions is dependent upon preliminary compound formation between solvent and solute. Careful conductivity determinations through the whole concentration range (pure solvent to pure solute) have here been carried out upon several series of typical two-component systems, for the different members of which the relative extent of compound formation in the liquid state has already been established<sup>2</sup> by a study of their freezing-point curves.

For the first series, systems of the general type  $HX:R.COOR'$  were chosen. It has been shown previously<sup>2</sup> that, in such systems, the extent of compound formation increases regularly as the radicals R and R' of the ester are made more electropositive, or as the radical X of the acid is made more electronegative. A suitable variation of all 3 radicals has been ensured in this work by selecting the following systems for examination:

<sup>41</sup> See pp. 1420–22.

<sup>1</sup> Kendall and Gross, *THIS JOURNAL*, **43**, 1416 (1921).

<sup>2</sup> Kendall and Booge, *ibid.*, **38**, 1712 (1916).

acetic acid (a typical weak acid) and trichloro-acetic acid (a typical strong acid) with each of the 3 esters, ethyl acetate, ethyl benzoate and benzyl benzoate.

For the second series, systems of the general type,  $HX:R.CO.R'$  were taken. Freezing-point data for such systems show<sup>3</sup> that here also the extent of compound formation increases as the radicals  $R$  and  $R'$  of the ketone are made more electropositive, or as the radical  $X$  of the acid is made more electronegative. The following representative systems were studied: acetic acid and trichloro-acetic acid with acetone and acetophenone.

For the third series, systems of the general type,  $HX:HY$  were selected. Compound formation between acids in pairs has been shown<sup>4</sup> to increase regularly with increasing diversity in the electro-affinity of the radicals  $X$  and  $Y$ . In this work acetic acid was taken as the fixed component  $HX$ , and acids of widely divergent character (trichloro-acetic, a typical strong acid; monochloro-acetic, a typical transition acid; and propionic, a typical weak acid similar to acetic) chosen as the variable component  $HY$ . A considerable range in compound formation through the series was thus obtained. This series was also still further extended<sup>5</sup> by including some examples of the type, acid: base, for which reliable data are already available.<sup>5</sup> An additional system of this class, acetic acid: formamide, was here investigated for comparison.

### Experimental.

**Purification of Materials.**—The nature of the experimental work rendered it necessary to take extreme precautions to ensure the elimination of even minute traces of impurities from all substances employed. The presence of impurities in quantities insufficient to exert any appreciable influence upon the freezing point or boiling point was frequently found to result in a very considerable change in specific conductivity.<sup>6</sup> A constant specific conductivity was therefore made the final criterion of purity. After other satisfactory physical constants had been obtained, purification was continued until no further lowering in the specific conductivity could be effected. Brief descriptions of the methods of purification adopted will be found under the separate systems below. Here the measure of success attained may be indicated by comparing the results of this work with the lowest values previously recorded. The association factors<sup>7</sup> and viscosities<sup>8</sup> for each liquid are included for convenience of reference in subsequent discussion.

TABLE I.—SPECIFIC CONDUCTIVITIES OF PURE LIQUIDS.

Liquid.	Association factor.	$\eta$ 25°.	$\kappa$ 25° (Kendall and Gross).	$\kappa$ 25° (previous record).
Ethyl acetate <sup>9</sup> .....	1.00	0.004239	$<1 \times 10^{-9}$	$4 \times 10^{-7}$
Ethyl benzoate.....	1.00	0.02014	$<1 \times 10^{-9}$	.....
Benzyl benzoate.....	1.00	0.08514	$<1 \times 10^{-9}$	.....
Acetone <sup>10</sup> .....	1.26	0.003065	$5.8 \times 10^{-8}$	$15 \times 10^{-8}$
Acetophenone <sup>11</sup> .....	1.16	0.01681	$5.5 \times 10^{-8}$	$18 \times 10^{-8}$
Acetic acid <sup>12</sup> .....	3.62	0.01121	$2.4 \times 10^{-8}$	$2 \times 10^{-8}$
Propionic acid <sup>13</sup> .....	$>1.0$	0.0102	$<1 \times 10^{-9}$	$7 \times 10^{-8}$
Monochloro-acetic acid. $>1.0$	.....	.....	$1.4 \times 10^{-6}$ (60°)	.....
Trichloro-acetic acid <sup>14</sup> . $>1.0$	.....	0.0397 (60°)	$6.2 \times 10^{-9}$ (60°)	$1 \times 10^{-7}$ (60°)
Formamide <sup>15</sup> .....	6.18	0.03358	$4 \times 10^{-6}$	$3 \times 10^{-6}$

**Temperature Regulation.**—Wherever practicable, determinations were carried out at 25°, in a large Freas thermostat electrically regulated to  $\pm 0.01^\circ$ . In the case of solutions containing considerable excess of trichloro-acetic or monochloro-acetic acid, it was not possible to obtain direct measurements at 25°, since the systems start to solidify above that temperature, and supercooling to any large extent in the presence of the platinum electrodes could not be successfully maintained. The curves for systems containing these acids as one component were consequently completed by carrying out determinations, where necessary, at a higher temperature (60°) and transposing the results so obtained to values approximately correct for 25° by the use of a temperature coefficient derived from the last solution measurable at the lower temperature. The assumption that the temperature coefficient is independent of concentration renders, of course, such transposed values rather uncertain, but as will be seen by reference to the diagrams<sup>16</sup> the portions of the curves so treated are of only minor importance, and the results obtained are sufficiently accurate to indicate the essential course of the completed curves. The determinations at 60° were carried out in a smaller thermostat, fitted with an Ostwald regulator and showing variations in temperature of less than  $\pm 0.05^\circ$ .

**Conductivity Measurements.**—The specific conductivities of the solutions examined varied from  $6 \times 10^{-8}$  to less than  $1 \times 10^{-9}$  mhos, the latter value constituting the lower limit of the measurable range with the apparatus employed. In order to obtain good sound minima with the more poorly conducting solutions, cells of the

<sup>9</sup> Kahlenberg and Lincoln, *J. Phys. Chem.*, 3, 12 (1899). Sammis (*ibid.*, 10, 593 (1906)) states that ethyl acetate shows zero conductivity, but does not indicate his limits of measurement.

<sup>10</sup> Walden, *Z. physik. Chem.*, 73, 263 (1910).

<sup>11</sup> Lincoln, *Trans. Wisconsin Acad.*, 12, II, 395 (1898-9).

<sup>12</sup> Patten, *J. Phys. Chem.*, 6, 654 (1902). It must be noted that Patten worked with cells possessing much larger constants than those here employed, and also used a short bridge. His value for  $\kappa$  can consequently be only an approximation, since it is right at the lower limit of measurable conductivities.

<sup>13</sup> Otten, *Diss.*, München, 1887.

<sup>14</sup> Whetham, *Phil. Mag.*, [5] 44, 1 (1897). The material employed was evidently very impure, since its m. p. (52°) was more than 7° below that of the acid used in this work.

<sup>15</sup> Davis and Putnam, *J. Franklin Inst.*, 180, 577 (1915). Only a very small fraction of material with  $\kappa = 3 \times 10^{-6}$  was obtained by these investigators, the formamide actually employed in their conductivity measurements having much higher values,  $\kappa = 7 \times 10^{-6}$  to  $15 \times 10^{-6}$ .

<sup>16</sup> Dotted curves, in the diagrams, indicate values reduced from 60°.

special type described by Beans and Eastlack<sup>17</sup> were used throughout. The electrodes were carefully platinized and the cell constants (which ranged, for different cells, between 0.007 and 0.009) were frequently redetermined during the course of the determinations. As noted by Beans and Eastlack, the passage of the current caused no appreciable heating effects with the solutions investigated. Capacity errors were tested for, and found to be within the errors of measurement.

The bridge employed was a 3-meter Leeds and Northrup instrument; the accuracy of the bridge calibrations and of the attached resistances was thoroughly checked throughout the work. Alternating current at 1000 cycles per second was obtained from a constant-speed high-frequency generator. The telephone receiver used was tuned to the same frequency.

Conductivity measurements were made, for each system, at a sufficient number of different concentrations to define the complete curve, the distance between successive points being varied to suit each particular case. Mixtures were made up by direct weighing, with the use of a Grethan pipet for the liquids. The molecular composition values tabulated below are accurate within  $\pm 0.05\%$ . The accuracy of the conductivity data does not approach this in order. For poorly conducting solutions ( $\kappa < 10^{-7}$ ) the error limit is from 1 to  $2 \times 10^{-9}$ . For solutions of higher conductivity, the values given are accurate to 0.5 or 1.0% for systems of the types acid: ester and acid:acid, and from 1.0 to 2.0 % for systems of the types acid: ketone and acid:base. The main source of error lies in the difficulty of preparing materials of constant purity. In particular cases (*i.e.*, in systems containing acetone or formamide) the limits of error may even exceed 2.0%, owing to the impossibility of keeping an adequately purified product entirely unchanged during the determinations. The problem here presents the same difficulties as does the preparation of ultra-conductivity water.<sup>18</sup>

Even the largest possible error which may thus be introduced, however, is negligible when the relative positions of the conductivity curves for different systems are compared, as will be seen below.

### Systems of the Type, Acid: Ester.

**Trichloro-acetic Acid: Ethyl Acetate.**—Trichloro-acetic acid (reputed c. p.) was dissolved in hot benzene and precipitated as fine crystals by rapid cooling. The crystals were repeatedly washed with cold benzene and the washings drained off. The residual crystals, with adherent benzene, were then liquefied by heating and the hot solution poured into a crystallizing dish over 99% sulfuric acid in a vacuum desiccator. Crystals of trichloro-acetic acid were deposited on cooling, and the last traces of benzene were completely removed by absorption and sulfonation in the sulfuric acid. The melting point of the product thus obtained,  $59.4^\circ$ , is the highest yet recorded.<sup>19</sup>

<sup>17</sup> Beans and Eastlack, *THIS JOURNAL*, 37, 2674 (1915).

<sup>18</sup> See Kendall, *ibid.*, 38, 2460 (1916).

<sup>19</sup> See Kendall and Booge, *ibid.*, 38, 1723 (1916). Owing to the extremely tremely hygroscopic character of trichloro-acetic acid, work on systems in which it formed one component was restricted to dry, cold days. Considerable patience was occasionally necessary.

Ethyl acetate was purified by careful fractionation, according to the recommendations of Wade.<sup>20</sup> The sample employed gave a boiling point of  $77.1 \pm 0.05^\circ$ .

The specific-conductivity data for the complete system are given below. Compositions of mixtures are expressed in molecular percentages; conductivities are given in reciprocal ohms  $\times 10^7$ ; the temperature is  $25^\circ$  unless otherwise noted. The results are also reproduced graphically in Fig. 1.

<sup>20</sup> Wade, *J. Chem. Soc.*, 87, 1656 (1905).

**Acetic Acid:Ethyl Acetate.**—Acetic acid was first partially purified by successive fractional crystallizations of c. p. glacial acid. It is an exceedingly laborious and wasteful process to remove all traces of water by this method,<sup>21</sup> consequently the following alternative procedure was devised. The freezing-point of a partially purified product was carefully determined and the water content calculated from the amount of divergence from the standard value, using the figures of De Visser.<sup>22</sup> The exact quantity of redistilled acetic anhydride necessary for the conversion of this water to acetic acid was then added and complete hydrolysis effected by refluxing the liquid at the boiling point for 30 hours, taking care to exclude moisture.<sup>23</sup> The acid so obtained was carefully fractionated and the main fraction (b. p.,  $117.8^\circ \pm 0.1^\circ$ ; m. p.,  $16.57^\circ \pm 0.05^\circ$ ) employed in the conductivity work. The results are given below and in Fig. 1.

Mol % acid.....	0.00	23.52	49.27	77.87	100.0
$\kappa \times 10^7$ .....	<0.01	0.05	0.12	0.20	0.24

**Trichloro-acetic Acid: Ethyl Benzoate.**—Ethyl benzoate, reputed c. p., was fractionated repeatedly under ordinary pressure. The fraction with constant boiling point  $212.9^\circ \pm 0.1^\circ$  was employed.<sup>24</sup>

Mol % acid	0.00	7.95	17.93	26.83	36.59	47.66	51.37	54.81

			(60°)	(60°)	(60°)	(60°)	(60°)	

**Acetic Acid:Ethyl Benzoate.**—

Mol % acid.....	0.00	10.15	28.78	44.07	61.45	74.69	84.60	91.74	100.0
$\kappa \times 10^7$ .....	<0.01	0.04	0.08	0.16	0.28	0.38	0.43	0.38	0.24

**Trichloro-acetic Acid:Benzyl Benzoate.**—Attempts to purify benzyl benzoate by distillation under ordinary pressure, as recommended by the Earl of Berkeley,<sup>25</sup> gave a product of inconstant specific conductivity, probably due to slight cracking at the high temperature required (corrected b. p.,  $323.0^\circ \pm 0.2^\circ$ ). An improved form of apparatus<sup>26</sup> for fractionation under constant low pressure (about 20 mm.) was devised, and a satisfactory product obtained by repeating the distillation of the best fraction until no further change in its physical constants could be effected.<sup>27</sup>

<sup>21</sup> See Bousfield and Lowry, *J. Chem. Soc.*, 99, 1432 (1911); DeVisser, *Rec. trav. chim. Belg.*, 12, 101 (1893). Ballo (*Z. physik. Chem.*, 72, 439 (1910)) claims that acetic acid and water form solid solutions.

<sup>22</sup> De Visser, *loc. cit.*, p. 118.

<sup>23</sup> Johnstone (*Trans. Nova Scotia Inst. Science*, 13, 199 (1913-14)) attempted this method, but found the specific conductivity of his product higher than at first. This he attributed to traces of HCl in the anhydride employed; more probably, however, it was due to incomplete hydrolysis.

<sup>24</sup> Timmermans, *Bull. soc. chim. Belg.*, 25, 316 (1911).

<sup>25</sup> Earl of Berkeley, *J. Chem. Soc.*, 109, 520 (1916).

<sup>26</sup> See Gross and Wright, *J. Ind. Eng. Chem.*, 13, 701 (1921).

<sup>27</sup> The m. p. of the final product was  $19.3^\circ \pm 0.05^\circ$ . Values as high as  $21^\circ$  are to be found in the literature (see Claisen, *Ber.*, 20, 647 (1887)), but such values, being based without exception upon measurements made by the capillary-tube method upon small amounts of material with unstandardized thermometers, are worthless for comparison. More recent work establishes  $19.4^\circ \pm 0.05^\circ$  as the most probable m. p. for a perfectly pure product (see Kendall and Monroe, *This Journal*, 43, 115 (1921)).

## Systems of the Type, Acid : Ketone.

Trichloro-acetic Acid : Acetone.—The difficulties encountered in the purification of acetone have been noted by many previous investigators.<sup>28</sup> Impurities other than water can be removed by forming and separating the bisulfite addition compound, hydrolyzing, and fractionating repeatedly. The real task, however, still remains—the total elimination of water. The method proposed by Shipsey and Warner<sup>29</sup> was attempted, but the resulting product (although satisfactory in its other physical constants) possessed too high a specific conductivity for use in this work. The procedure finally resorted to was that recommended by Timmermans<sup>30</sup>—dehydration by means of phosphorus pentoxide. Acetone of low conductivity was thus obtained and carefully fractionated. In spite of all precautions, however, it was found that the conductivity of the purest material prepared could not be kept constant, but increased slowly on standing.<sup>31</sup> Freshly fractionated acetone was consequently always employed in the preparation of the solutions listed below, and conductivity measurements carried out as rapidly as possible, consistent with accurate work. Even so, great difficulty was experienced in duplicating some of the individual points in trichloro-acetic acid—acetone mixtures, the deviations between different preparations amounting in some cases to 5%. The uncertainty thus introduced in the conductivity data, however, does not affect their relative magnitude as compared with the values for other systems, as may be seen most readily by reference to Fig. 2.

$\kappa \times 10^7$ .....		4.32	3.12	1.33	0.24				

<sup>28</sup> See, for example, Walden, *Z. physik. Chem.*, **46**, 124 (1903); Timmermans, *Bull. soc. chim. Belg.*, **24**, 244 (1910).

<sup>29</sup> Shipsey and Warner, *J. Chem. Soc.*, 103, 1255 (1913).

<sup>30</sup> Timmermans, Reference 28. A considerable loss of material results from the action of the pentoxide on the acetone itself.

<sup>31</sup> This increase may be accounted for either by the absorption of minute amounts of impurities which affect the conductivity tremendously (as CO<sub>2</sub> from the air does in the case of water) or by the steady progress of isomeric (keto-enol) or polymeric changes on standing.

Fig. 2.—Systems of the type acid ketone. Curve A, trichloro-acetic acid:acetone; Curve B, trichloro-acetic acid:acetophenone; Curve C, acetic acid:acetone.

**Trichloro-acetic Acid:Acetophenone.**—Acetophenone (reputed c.p.) was dehydrated with phosphorus pentoxide and repeatedly fractionated<sup>32</sup> under ordinary pressure. The material finally employed was of constant boiling point ( $202.3^\circ \pm 0.1^\circ$ ), with specific conductivity<sup>33</sup>  $5.5 \times 10^{-8}$ .

The results given below are also reproduced graphically in Fig. 2.

Mol % acid	0.00	6.83	14.04	24.60	36.92	44.15	48.42	53.23

Mol % acid	95.16	100.0						
$\kappa \times 10^7$	1.48	(60°)	0.06	(60°)				

**Acetic Acid:Acetophenone.**—

Mol % acid	0.00	6.91	16.39	25.39	33.29	40.98	49.55	57.22
$\kappa \times 10^7$	0.55	2.86	3.33	3.51	3.58	3.46	3.44	3.20
Mol % acid	65.87	69.68	77.20	82.79	90.74	100.0		
$\kappa \times 10^7$	2.83	2.59	2.26	1.75	1.11	0.24		

<sup>32</sup> The acetophenone was carefully decanted off from the pentoxide before distilling so as to avoid the possible formation of benzoic acid during fractionation. Compare Klago and Allendorf, *Ber.*, 31, 1298 (1898).

<sup>33</sup> The value given here could probably be still further reduced, since very small fractions with somewhat lower conductivities were obtained.

## Systems of the Type, Acid:Acid.

**Trichloro-acetic Acid:Acetic Acid.**—The results for this system are shown in graphic form in Fig. 3.

Mol % trichloro-acetic acid	0.00	4.86	10.43	18.72	23.72	27.67	31.75	37.99
$\kappa \times 10^7$	0.24	1.67	3.67	6.37	8.05	8.31	8.08	7.10

**Monochloro-acetic Acid:Acetic Acid.**—Monochloro-acetic acid was recrystallized from benzene and fractionated under atmospheric pressure. A large constant-boiling fraction was obtained, which was again crystallized several times from benzene, as described under trichloro-acetic acid.<sup>34</sup> The final product possessed an exceptionally high specific conductivity<sup>35</sup> for a pure substance,  $\kappa_{60^\circ} = 1.4 \times 10^{-6}$ . Further

<sup>34</sup> See p. 1429.

<sup>35</sup> No previous values are recorded in the literature. It is of interest to note, however, that the dielectric constant is also exceptionally high (Walden, *Z. physik. Chem.* 70, 569 (1909)).

attempts at purification, however, did not result in any reduction. The specific conductivity curve for the system is shown in Fig. 3.

Mol % monochloro-acetic acid	0.00	7.25	14.76	23.02	30.50	40.16	49.60	55.20
$\kappa \times 10^7$	0.24	0.98	1.92	2.99	3.84	4.55	5.03	5.27

	(60°)	(60°)	(60°)	(60°)	(60°)	(60°)		

**Propionic Acid : Acetic Acid.**—Propionic acid, with no measurable conductivity, was prepared from a reputed C. P. product by fractional distillation. The results are reproduced in Fig. 3.

Mol % propionic acid.....	0.00	7.51	28.80	54.59	74.63	91.14	100.0
$\kappa \times 10^7$ .....	0.24	0.18	0.13	0.07	0.06	0.03	<0.01

**Formamide : Acetic Acid.**—The formamide employed had been prepared by heating ammonium formate. The removal of traces of decomposition products formed during this preparation was found to be a matter of extreme difficulty. Partial crystallization did not prove successful,<sup>36</sup> but a product of sufficient purity was finally secured by careful fractionation *in vacuo*. The specific conductivity of the best fraction obtained was  $4 \times 10^{-6}$ . The amount of this fraction was too small for making up a complete series of solutions, and the values given below were derived with the use of material of a higher conductivity;  $\kappa = 9 \times 10^{-6}$ . Previous investigators<sup>37</sup> have encountered similar difficulties in the preparation of a standard product and have adopted the same procedure. While the results thus obtained are naturally not so reliable as in the case of other systems, yet for purposes of comparison their degree of accuracy is amply sufficient (see Fig. 3).

Mol % formamide.....	0.00	4.00	11.08	21.05	28.42	36.42	44.74	53.15

### Consideration of Results.

**Pure Liquids.**—The connection between association and self-ionization in pure liquids, discussed in the preceding article, is typically illustrated by the data presented in Table I. The esters, which are practically non-associated, also exhibit practically zero conductivity. The ketones and acids, with higher degrees of association, possess specific conductivities in general of a higher order. In view of the uncertainty in some of the values,<sup>38</sup> this qualitative agreement with theory is all that can be demonstrated here. For strict comparison purposes, moreover, differences in viscosity and ionic mobilities in the various liquids must also be taken into account.

<sup>36</sup> Braun, *THIS JOURNAL*, **40**, 793 (1918).

<sup>37</sup> Davis and Putnam, *J. Franklin Inst.*, **180**, 577 (1915). These investigators find that solutions with formamide as one component show little difference in specific conductivity, whether material of  $\kappa = 7 \times 10^{-6}$  or  $\kappa = 15 \times 10^{-6}$  is employed.

<sup>38</sup> Some of the figures given (*e. g.*, for formamide) are certainly too high. In most cases, however, it is doubtful whether further attempts at purification would lower the specific conductivity appreciably. Such drastic changes in the accepted values as have here been effected are, at any rate, not likely to recur.

**Solutions.**—The conductivities of the mixtures investigated are, except in such cases where the "diversity factor" is negligible,<sup>39</sup> considerably in excess of those of the pure components, as will be evident by inspection of the diagrams. The maxima on the curves are listed below. Where compounds have been isolated by the examination of the freezing-point curve of the system, their formulas and melting points are also indicated. In order to economize space in presenting formulas, the letters A and B are used throughout to indicate the first and second components of each system.

TABLE II.—MAXIMUM SPECIFIC CONDUCTIVITIES OF MIXTURES.

In no case does the position of the maximum point correspond with the composition of the isolable compound, or indeed, except by chance, with any simple molecular proportions of the two components. No exact correspondence, however, although frequently sought for by earlier investigators,<sup>41</sup> is to be expected, even under the assumption here made that the conductivity of the mixtures is to be ascribed to the ionic instability of the addition compounds formed. For, in the first place (as may be seen from Table I), considerable changes in viscosity occur in any given system as composition is varied, and such viscosity changes will necessarily be accompanied by variations in the mobilities of the ions. The point of highest ionic concentration is not, in consequence, the point of highest specific conductivity.<sup>42</sup> A second disturbing factor of equal importance is the change in average ionic complexity with change in composition. Addition compounds other than the equimolecular are certainly present in solutions of the types here studied,<sup>43</sup> even although their concentration

<sup>39</sup> E. g., in the systems, acetic acid: propionic acid; acetic acid: ethyl acetate.

<sup>40</sup> English and Turner, *J. Chem. Soc.*, 107, 777 (1915).

<sup>41</sup> For references see Carrara, *Ahrens' Sammlung*, 12, 403 (1908); Dhar, *Z. Elektrochem.*, 20, 57 (1914).

<sup>42</sup> The viscosity curves of the systems here examined will be presented in a subsequent paper.

<sup>43</sup> See Kendall, Booge and Andrews, *THIS JOURNAL*, 39, 2305 (1917).

may not be sufficient to permit of their actual isolation. The relative amounts of the various compounds will vary with the solution, each compound (according to the law of mass action) being present in maximum quantity in a solution of its own composition. Each compound, furthermore, will have its own particular "ionic instability," the most simple in type, the equimolecular, being also the least unstable. We can hardly postulate, therefore, a *maximum* specific conductivity for the solution of equimolecular composition when compounds of more complex character, although present in smaller amounts, may exhibit very superior tendencies towards ionic disintegration. In certain cases, indeed, where the equimolecular compound is exceptionally stable and where other compounds, much less stable in comparison, are also formed in quantity, we may expect to find not a maximum but a *minimum* specific conductivity for the equimolecular solution. Actual examples of this type are discussed later.

How far the predicted parallelism between compound formation and ionization is experimentally realized in the systems examined may now be briefly discussed.

**Systems of the Type Acid:Ester.**—According to the rules outlined in the introduction, solutions of trichloro-acetic acid with ethyl acetate should show the highest conductivities of all those here studied, followed by solutions of the same acid with ethyl benzoate and benzyl benzoate. The three esters with acetic acid should exhibit very much lower conductivities.

Inspection of Fig. 1 and Table II will show that this is the case. At the one extreme we have the system trichloro-acetic acid:ethyl acetate, with a maximum specific conductivity of  $10 \times 10^{-7}$ , at the other extreme the system acetic acid:benzyl benzoate, with conductivities immeasurably small. The only break in the regularity consists in the slight superiority of the system acetic acid:ethyl benzoate over the system acetic acid:ethyl acetate. The conductivities throughout both of these systems, however, are only of the same order as that of pure acetic acid.

**Systems of the Type Acid:Ketone.**—Employing our theory as before, we may predict here that solutions of trichloro-acetic acid with acetone will possess higher conductivities than those of the same acid with acetophenone, and that the two ketones with acetic acid will give much more poorly conducting solutions. Again the experimental results are in agreement, as may be seen from Fig. 2 and Table II.

The conductivities in this series are very much greater than in corresponding ester systems; for example, the system trichloro-acetic acid:acetone shows a maximum specific conductivity of  $225 \times 10^{-7}$ . This must be ascribed to the "unsaturation factor," discussed in the preceding article,<sup>44</sup> the ketones being typical associated liquids while the esters are practically non-associated.

<sup>44</sup> P. 1421.

**Systems of the Type Acid : Acid.**—While very high conductivities are not to be expected here, yet the large range in the "diversity factor" through the series should be reflected in correspondingly large variations in the specific conductivities obtained. In actual fact, we find the system of two very dissimilar acids trichloro-acetic acid:acetic acid with a maximum value of  $8.3 \times 10^{-7}$ , while the system of two essentially similar acids propionic acid:acetic acid possesses negligible conductivities throughout. The curve for the system monochloro-acetic acid:acetic acid is intermediate in its position.

**Systems of the Type Acid : Base.**—The increase in the "diversity factor" here results in vastly increased compound formation and specific conductivity in the solutions. Thus even an exceedingly weak base such as formamide gives an isolable addition product with acetic acid, and the maximum specific conductivity exceeds  $600 \times 10^{-7}$ . Water, another very weak base, gives a much more pronounced maximum.<sup>45</sup> Solutions of stronger bases, such as the substituted alkyl and aryl amines, give still higher conductivities with acetic acid. Our uncertainty as to the actual strengths of such bases renders close comparison difficult, yet it is significant that the order of the maxima obtained by Konovalov<sup>46</sup> for aniline and its methyl-substituted derivatives with acetic acid parallels the order of the dissociation constants of these bases<sup>47</sup> in aqueous solution (*i. e.*, methyl aniline > aniline > dimethyl aniline). With the much stronger arylamines (amylamine and isobutyl amine) and acetic acid, Patten<sup>48</sup> obtained specific conductivity curves showing *two distinct maxima*, one on either side of the equimolecular mixture, which thus exhibits a *minimum* conductivity. The diversity between the two components is here, evidently, sufficiently pronounced to induce the formation in quantity of compounds more complex and ionically much more unstable than the simple equimolecular compound. An exactly similar curve is given by a more familiar system of the same type, sulfuric acid:water,<sup>49</sup> a minimum specific conductivity corresponding with the stable equimolecular compound,  $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$ . Methyl and ethyl alcohols with hydrogen chloride may be cited as additional examples, already discussed from the same viewpoint by Maass and McIntosh.<sup>50</sup>

### Compound Formation and Electro-affinity.

The results of the present article may also be interpreted—reversing for the moment the sequence of the argument—as justifying the tacit assump-

<sup>46</sup> Konovalov, *Wied. Ann.*, 49, 733 (1893).

<sup>47</sup> Landolt-Börnstein, "Tabellen," 1912, p. 1179.

<sup>48</sup> Patten, *J. Phys. Chem.*, 6, 554 (1902).

<sup>49</sup> Kohlrausch, Landolt-Börnstein, "Tabellen," 1912, p. 1099.

<sup>50</sup> Maass and McIntosh, *THIS JOURNAL*, 35, 535 (1913).

tion made throughout this series that the "diversity factor" for the constituent groups in *non-aqueous* solutions may be postulated directly from the results obtained by comparison of acidic (or basic) strengths or by differences in electrode potentials in *aqueous* solutions. It has been demonstrated here, for example, that trichloro-acetic acid is much stronger than acetic acid not only in water, but in other basic solvents such as ketones and esters.<sup>51</sup> When acetic acid is employed as a solvent, an acid of similar strength in aqueous solution (propionic acid) is practically a non-electrolyte, while stronger acids (monochloro-acetic, trichloro-acetic) and bases (formamide, water, aniline, amyl amine) give increasingly greater specific conductivities the greater the divergence in character exhibited by the variable group in aqueous solutions.<sup>52</sup> We can therefore deduce the general rules that the order of the electro-affinities of different radicals is substantially the same whatever the solvent, and that increasing diversity in the electro-affinities of the constituent groups runs parallel to association in pure liquids, to compound formation in binary solutions, and to ionization in both.<sup>53</sup>

### Summary.

The complete specific-conductivity—composition curves for 14 systems of the types: acid:ester, acid:ketone, acid:acid and acid:base have been determined with the greatest possible degree of accuracy. New standards of purity (as demonstrated by lowering of accepted specific-conductivity values) have been set for the majority of the substances employed.

The conductivities of solutions of the above types are, in general, considerably in excess of those of the pure components, and increase uniformly with increasing diversity in character (*i. e.*, in the positive or negative nature of the constituent radicals) of their components. The results here obtained have been correlated with those derived from freezing-point measurements upon similar systems, and the validity of the fundamental relationships between compound formation and ionization in solutions, postulated in the preceding article, has been confirmed.

In subsequent papers the viscosity curves for the above systems will be presented and the theoretical discussion continued.

## NOTES ON SILVER BROMATE.

By J. H. REEDY.

Received January 13, 1921.

**Variation in Potential.**—In a study of silver electrodes which the writer made a few years ago, it was noticed that the potential of the electrode  $\text{Ag} | \text{solid AgBrO}_3 | 0.1 \text{ M KBrO}_3$ , when freshly prepared, was not definite, but underwent a progressive change for some time. This change frequently amounted to more than 100 millivolts, and was always in the direction indicating a decrease in the solubility of the silver bromate. The silver bromate used was of "technical" grade, and according to the statement of the manufacturers, was made by the action of an excess of bromine on silver nitrate solution. Its composition was therefore a mixture of silver bromate and silver bromide in the molar ratio 1:5. Representative results (referred to the 0.1 *N* calomel electrode as +0.342 volt) are given in Table I, the temperature being 25°. In all cases, the electrode, upon standing, finally gave a value of +0.631 volt.

TABLE I.—VARIATION IN THE ELECTRODE  $\text{Ag} | \text{AgBrO}_3$  IN 0.1 *M*  $\text{KBrO}_3$ .

Time, days.	Electrode potential. Volt.
0	+0.795
1	+0.643
2	+0.641
3	+0.634
4	+0.631
5	+0.631

**Purification.**—To meet the possibility that this change of potential might be due to the presence of some metastable substance in the impure silver bromate, this material was purified by extraction with hot water, using the apparatus shown in Fig. 1. The recrystallized silver bromate was collected on a filtering plate P, washed several times with ice water, and finally dried in a vacuum desiccator. Silver bromate prepared in this way is pure white, and appears when dry to be wholly unaffected by light. The wet salt was not found to be so stable.<sup>1</sup> A portion of the pure material was placed in a carefully cleaned tube, covered with water, and the top of the tube sealed off. After standing several weeks, the side next to the window showed a slaty-gray color, while the rest was only slightly affected. To see if there was any change in volume during the darkening, due to the formation of an insoluble gas (oxygen, supposedly), some wet silver bromate was sealed in a tube with a manometer containing pure liquid paraffin attached. After standing for more than a year there was no displacement of the levels in the arms, as shown by a "blank"

<sup>1</sup> Cf. Stas, *Mem. de l'Acad. r. de Belgique*, 35, 82, 118.

apparatus alongside. This darkening effect is very marked when wet crystals are heated, though the dry salt seems to be quite stable. Instead of decomposing about  $150^{\circ}$ , as was reported by Stas, the carefully

Fig. 1—Recrystallization of silver bromate.

purified salt was heated above its melting point ( $308$  to  $310^{\circ}$ ) without visible decomposition. The introduction into the heated salt of a foreign substance, as a little dust, was found to cause violent explosion.

The purity of the recrystallized product was determined as follows. Samples were weighed in evaporating dishes and converted into silver bromide by evaporation to dryness with an excess of pure hydrobromic acid solution and dried at  $120^{\circ}$  to  $125^{\circ}$ . The weight of the silver bromide residue indicated degrees of purity varying slightly with the batch of crystals used. The purity usually ranged from 99.6% to 99.8%, though in one case, when the sample had been heated to  $130$ – $135^{\circ}$  for several hours, a purity of 100% was found. This deviation from absolute purity might possibly be due to the presence of a small amount of the unknown silver perbromate; however, the most natural assumption is that the foreign substance is water. This was the opinion of Stas, who reported that the last traces of water in silver bromate could not be driven off below its decomposition point.

**Dimorphism.**—Potential measurements made on electrodes using the purified silver bromate gave even more erratic results than the crude

silver bromate-bromide mixture. On the other hand, silver bromate prepared by the interaction of silver nitrate and potassium bromate solutions at ordinary temperatures gave the potential of  $+0.631$  volt immediately. It was noticed at this point that there was a difference in the crystalline form of the silver bromate prepared from hot and cold solutions. The crystals formed by sudden cooling were hair-like, while those from the cold solutions were tetragonal crystals. Figs. 2 and 3 are from microphotographs of these forms. The habit of the hair-form in

Fig. 2.—The hair form.

Fig. 3.—The tetragonal form.

forming crosses as shown in the figure is the frequent, but not the universal behavior of these crystals. Upon slow cooling of a hot saturated solution, however, the tetragonal form was the main product. While the hair-form is truly stable only at high temperatures, by sudden cooling (that is, "freezing the equilibrium") it may be carried over in a metastable condition into the region of the tetragonal form. In the dry condition this metastable form seems to persist indefinitely, and even in solution the reversion into the common form may be surprisingly slow. As a result of the greater solubility of the hair-form, electrodes whose solutions contain it show elevated potentials. The fact that Retgers<sup>2</sup> has already pointed out that silver chlorate shows the phenomenon of dimorphism had been assumed by the writer as presumptive evidence that the bromate also might crystallize in two forms.

**Solubility and Transition Point.**—At the suggestion of the writer, Mr. S. J. Gould has determined the solubility curve for silver bromate in water and the transition point of the two forms.

Samples of saturated solutions were taken at various temperatures between  $25^{\circ}$  and  $100^{\circ}$ , and weighed in glass-stoppered bottles. Due precautions were taken against change in concentration owing to cooling

<sup>2</sup> Retgers, *Z. physik. Chem.*, 5, 438 (1890).

during the transfer. After cooling and weighing, the amount of silver bromate was determined by adding an excess of potassium iodide solution, acidifying with dil. hydrochloric acid, and titrating the liberated iodine with standard thiosulfate solution. Table II shows the solubilities as

TABLE II.—SOLUBILITY OF  $\text{AgBrO}_3$ .

Temperature. ° C.	Solubility in 100 g. of $\text{H}_2\text{O}$ . G.
25	0.196
30	0.227
35	0.269
40	0.316
45	0.371
50	0.433
55	0.497
60	0.570
65	0.648

75	0.832
80	0.936
85	1.055
90	1.325

read from the curve and Fig. 4 the curve itself.

The solubility value for the stable form at  $25^\circ$  has been confirmed by e. m. f. measurements. Since there is some doubt as to the exact value of the normal silver electrode, a cell of the concentration type is desirable for this work. The combination used was  $\text{Ag}[\text{AgBrO}_3|\text{solid } 0.1 M \text{ KBrO}_3 \text{ sat. w. AgBrO}_3|\text{Conc. KNO}_3|0.1 M \text{ AgNO}_3|\text{Ag}]$ . This cell gave a potential of 0.1193 volt at  $25^\circ$ . Assuming that the onization of 0.1  $M$  potassium bromate solution is 82.5%, and of saturated silver bromate solution in 0.1  $M$  potassium bromate solution is 98% (the same as for potassium bromate and silver nitrate at the corresponding concentration), a solubility of 0.00827 mole per liter, or 0.1955 g. per 100 g. of water, is indicated.

No indication of a break in the solubility curve appears until near the boiling point of the

Fig. 4.—The solubility of silver bromate.

solution, where some apparently irregular values are found. The stations on the curve *BT* (Fig. 4) were obtained from solutions which had been allowed to boil for some time, the samples being taken after slight cooling. Evidently these values are somewhat uncertain. High confidence is placed in the values given in the curve *AT*. Solubility data may be said to indicate a transition point near  $98.5^{\circ}$ , with a possible error of  $0.5^{\circ}$ .

The dilatometer method gave practically the same value for the transition point. A saturated hydrocarbon oil of high boiling point, obtainable

Fig. 5.—Dilatometer readings for silver bromate in "Nujol."

commercially, was used as the liquid. Readings are plotted in Fig. 5, and a transition point of about  $98.5^{\circ}$  is again indicated. The apparent break in the curve at about  $104^{\circ}$  is due to the fact that a gas begins to be evolved near that point.

**A Standard in Iodimetry.**—In view of the stability of silver bromate and the ready determination of its purity, its suitability as a standard in iodimetry suggests itself, and was investigated in the following way. The purity of the silver bromate used was determined

by converting it into silver bromide by the hydrobromic acid treatment described above. Samples of approximately one g. each were weighed into 250 cc. volumetric flasks, 150 cc. of water and an excess of potassium iodide added and the mixture was heated for some time on a steam-bath. In this way the silver bromate is completely converted into silver iodide and potassium bromate. The contents of the flask were then cooled and made up to 250 cc. Samples of 25 cc. each were acidified with dil. hydrochloric acid and titrated with sodium thiosulfate solution. The usual arsenious oxide method, using the highest grade of arsenic trioxide available, gave a titer appreciably higher than the silver bromate, *viz.*, 0.2%. This indicated that the purity of the silver bromate was greater than that assumed, or that the purity of the arsenic trioxide was less than 100%. Later, after recrystallizing the arsenic trioxide from dil. hydrochloric acid solution and subliming

it very carefully at as low a temperature as possible so as to prevent decomposition into metallic arsenic and oxygen, results were obtained which checked with the silver bromate within 0.05%. This indicates that while silver bromate may have a somewhat higher oxygen equivalent than arsenic trioxide, this defect is fully compensated by its greater definiteness.

**Gas Evolved upon Heating.**—It was noticed that a gas was evolved when silver bromate was heated in contact with water to about 100°. The same thing was found in the dilatometer determination in which the liquid medium was a saturated paraffin oil. The gas was assumed at first to be oxygen in the first case, and oxygen or carbon dioxide in the second. The fact that there was no sensible change in the composition of the silver bromate led to a closer investigation of this phenomenon. An apparatus was devised for heating the salt in contact with these liquids and catching the gas evolved. An atmosphere of hydrogen was kept above the liquids so as definitely to exclude air. The gas in both cases turned out to be a mixture of oxygen and nitrogen in practically the proportion occurring in the atmosphere. Spectroscopic examination gave no evidence of anything else. In the case of water as the liquid, 1 gram of silver bromate yielded during heating for 3 or 4 weeks at 90 to 100° slightly more than 4 cc. of gas. With the oil it gave a little less. It is supposed that the air was occluded during the precipitation of the crystals, or else absorbed later. The latter supposition is favored by the fact that the silver bromate was always precipitated from hot solutions.

This absorbed air suggests an alternate theory for the deviation of the purified silver bromate from 100% purity. The weight of the 4 cc. of air absorbed by one gram of the salt would amount to an impurity of about 0.5%, just as found above.

### Summary.

1. Silver bromate exists in dimorphic forms, *viz.*, tetragonal pyramids, stable at ordinary temperatures, and hair-like crystals, stable near 100°.
2. The variations in the potential of silver bromate electrodes are due to the presence of the metastable hair-like form, which shows a higher solubility than the tetragonal form.
3. Dry silver bromate is stable toward light and heat, but in the presence of water darkens slowly at low temperatures, and rapidly at high temperatures.
4. Silver bromate may be used as a standard in iodimetry.
5. Silver bromate crystals absorb an appreciable amount of air which is slowly given up at high temperatures.

## THE RATES OF HYDROLYSIS OF THE RARE EARTH CARBONATES AND THE SERIAL ORDER OF THE RARE EARTH ELEMENTS.

BY PAUL H. M.-P. BRINTON AND C. JAMES.

Received February 14, 1921.

### Introduction.

If the elements of the rare earth group are arranged in the order of increasing atomic weights, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, (Y), Er, Tm, Yb, Lu, Ct, it is found that in general this series represents the order of progressive variation in a number of other properties of the compounds of these elements. This *Serial Order*, as it is called, represents the order of solubilities of many series of rare earth salts, and therefore, usually, the order in which the compounds of the elements separate from solution in the operations of fractional crystallization. The order of decomposition of the nitrates on heating, and the order of precipitation by gradual addition of hydroxyl ion are also in general harmony (inversely) with this series, so that the series seems to represent the order of decreasing basicity of the elements.

A number of inconsistencies exist, however. Thus yttrium, with an atomic weight far below that of lanthanum, is placed, by general considerations of the solubilities of its compounds, between holmium and erbium; while the order of precipitation by ammonium hydroxide shows that its relative basic strength places it about with neodymium. Measurements of the dissociations of the anhydrous sulfates<sup>1</sup> indicate a degree of basicity for yttrium second only to that of lanthanum, admittedly the most strongly basic of the rare earths. By this same method samarium is given a place between gadolinium and terbium, and by fractional precipitation with ammonium hydroxide<sup>2</sup> samarium falls in the same position. Solubility considerations, on the other hand, place samarium between neodymium and europium in the serial order; and this same position has been accorded samarium by a study of the hydrolysis of sulfates.<sup>3</sup>

With a view to securing further data on the relative basicities and the serial order of the rare earth elements we have studied the rates of hydrolysis of the carbonates of 12 of these elements. In briefest outline,

<sup>1</sup> Wöhler and Gründzweig, *Ber.*, 46, 1726 (1913).

<sup>2</sup> de Boisbaudran, *Compt. rend.*, 111, 393 (1890); Benedicks, *Z. anorg. Chem.*, 22, 398 (1900).

<sup>3</sup> Katz and James, *THIS JOURNAL*, 36, 779 (1914).

the method was to prepare accurately standardized solutions of the rare earth sulfates, to add equivalent amounts<sup>4</sup> of each sulfate solution to separate portions of 0.5328 g. of purest sodium carbonate, and to heat for given lengths of time, under carefully controlled temperature conditions. The carbon dioxide resulting from the hydrolysis was weighed. Volume, and other conditions were maintained as uniform as possible in all experiments.

### Preparation of Materials.

The methods of separation and purification of the compounds of the various elements considered in this paper have been described elsewhere,<sup>5</sup> and need not be repeated here.

The method of preparing the sulfate solutions was the same for all the solutions. The oxide finally obtained from ignition of the purest oxalate was dissolved in the smallest possible amount of hydrochloric acid. Slightly more than the theoretical amount of sulfuric acid was then added to the somewhat diluted solution, and this was then poured into a large excess of 95% ethyl alcohol. The precipitated sulfate was thoroughly washed with alcohol, and dehydrated by heating to 280–300°. The anhydrous sulfate thus obtained was dissolved in ice-cooled water. By evaporating to small volume in a bath of boiling water the hydrated sulfate was deposited in crystalline form. The crystals were filtered, and washed repeatedly with small amounts of boiling water until no trace of acid reaction could be detected in the washings. The crystals were allowed to stand over sulfuric acid in a desiccator for a day, and then dissolved in carbon dioxide free water to make a 0.1 *N* solution. The solution was standardized by precipitating pipetted samples as the oxalate, and igniting to the oxide,  $R_2O_3$ .

The only deviations from the above methods of standardization were the following: ytterbium was precipitated by ammonium hydroxide, owing to the considerable solubility of the oxalate; praseodymium was weighed as the oxide  $Pr_2O_3$ , after ignition in a current of hydrogen; terbium was weighed as  $Tb_4O_7$ , after ignition in the air.

Figures showing the concordance of these determinations may be replaced by the statement that the most discordant pair of the duplicates was in the case of ytterbium, which gave 0.3308 g. and 0.3301 g. of ytterbium oxide.

Sodium carbonate was prepared by saturating water at 60° with the purest sodium hydrogen carbonate of commerce. Carbon dioxide was passed into the filtered solution until cold, and the deposited sodium hydrogen carbonate was heated in platinum at 270 to 300° for several hours. 102.218 g. lost only 4. mg. on heating for 2 hours more at the same temperature; so it was heated for 1 hour after the last weighing, cooled in a desiccator over sulfuric acid, and quickly transferred to small stoppered bottles. 1.9796 g. of the sodium carbonate yielded on evaporation with sulfuric acid and gentle ignition with ammonium carbonate, 2.6547 g. of sodium sulfate. This agreed with the theoretical amount to within 4 parts in 10,000, so the sodium carbonate was considered pure enough for our purposes.

### Experimental.

The reaction chamber was a 500-cc. round-bottom flask with a neck

<sup>4</sup> Equivalent amounts of rare earth sulfate and sodium carbonate were used in order to avoid the formation of double carbonates or double acid salts. Such compounds as these are very characteristic of the rare earth metals.

<sup>5</sup> Vid. James and co-workers, *ibid.*, 1907 to date.

15 cm. long. Through one hole of the stopper a glass tube passed almost to the bottom of the flask, and the outer end of this tube could be connected with a funnel for the introduction of liquid, or with a large soda-lime tower for the purification of incoming air. Through the other hole of the stopper a 24-cm. bulb condenser was vertically set. Following the condenser was a train consisting of a large U-tube filled with sulfuric acid, a long horizontal calcium chloride tube, a Geissler potash bulb with a calcium chloride guard tube, and then another sulfuric acid tube, beyond which was the aspirator bottle.

The heating was accomplished by a gas flame 7.5 cm. high, with an inner cone 2.5 cm. high. The bottom of the flask was 4 cm. above the top of the burner. All draughts were excluded, and a pressure-equalizing tank between the burner and the main gas supply insured uniformity of flame.

In making a run, exactly 0.5328 g. of sodium carbonate was rinsed into the flask with 25 cc. of water. (All water used in these experiments was previously freed from carbon dioxide by boiling, and then cooled with the usual precautions.) The flask and train were then freed from carbon dioxide by aspirating several liters of pure air through. Next, the weighed potash bulb was placed in the train, and an amount of rare earth sulfate solution chemically equivalent to the sodium carbonate was introduced through a funnel attached to the tube leading to the bottom of the reaction flask, and this was rinsed with enough water to give a volume of 229.12 cc. This volume, and the weight of sodium carbonate were empirical, resulting from the experimental conditions of the first run, and maintained as standard throughout the series. The funnel was disconnected, the large soda-lime tower connected in its place, and aspiration was then started at the rate of 2.5 liters per half-hour. The flame was next placed under the flask, and the heating continued for exactly 30 minutes after incipient ebullition. The flame was then turned out and the "sweeping" with pure air continued for exactly 20 minutes. The potash bulb was weighed with the usual precautions, placed back in the train, the boiling and "sweeping" being repeated exactly as before. This operation was usually repeated 6 to 8 times with each sample, and the percentage hydrolysis calculated for each half-hour boiling period. Duplicates were run on all the elements considered in this paper with the exception of europium, terbium, and thulium, of which we had amounts sufficient for one run only.

Below are given the results of the experiments, giving the percentage hydrolysis, (*i. e.*, the amount of carbon dioxide given off, divided by the total carbon dioxide originally present in the system), at the end of each half-hour period.

The degree of accuracy of the individual determinations may be judged by the concordance in the results of analyses of the duplicate samples. While the concordance is not as close as might be desired in certain classes of measurements, yet it seems fair to assume that the position of an element in this series is not rendered doubtful by the limitations of the experimental methods used. Thus it will be seen that in the first (which

is the most important) stage of each run the highest figure for one element is lower than the lowest figure of the next higher element.

The results are graphically shown in Fig. 1, in which the percentages hydrolyzed are plotted against the time of boiling.

Fig. 1.

### Discussion of Results.

The behavior of lanthanum and cerium<sup>III</sup> is abnormal in comparison with the others. Hydrolysis seems to reach its limit in the first half-hour with these elements, while with the others there is a continuous, gradually decreasing amount for each additional period of boiling. That cerium should show a different behavior is not surprising, since cerium is really a fourth group element, and is not to be regarded as a "rare earth" element. Lanthanum also shows certain variations from the strict rare earth group.<sup>6</sup> It gives no absorption spectra, it finds a place in the old periodic table, and in general shows greater characteristic individuality than do the other members of the rare earth group.

The position of yttrium is interesting. General considerations of the solubilities of its compounds places yttrium between holmium and erbium, but the order of precipitation by ammonia places it about with neodymium. Our results on the hydrolysis of yttrium carbonate place the element between dysprosium and thulium, and while holmium and erbium were

<sup>6</sup> Hauser and Wirth, *Z. anal. Chem.*, 47, 395 (1908).

not available for our tests, these two also come between dysprosium and thulium in the generally accepted serial order, and it is not improbable that had we been able to investigate holmium and erbium they would have found a place on each side of yttrium. From our results the position accorded to yttrium (just below lanthanum in basicity) by Wöhler and Grünzweig<sup>7</sup> from their study of the dissociation of the anhydrous sulfates seems to be erroneous.

Hydrolysis of the carbonates places europium between samarium and gadolinium, and lends additional support to the serial order established by solubility relations. This is at variance with the order of precipitation by ammonia, as well as that indicated by the sulfate tensions investigated by Wöhler and Grünzweig.

It is worthy of note that a large space occurs in our Fig. 1 between neodymium and samarium. This is in harmony with the idea derived from study of the atomic numbers<sup>8</sup> that there is an undiscovered rare earth element with a position between those of neodymium and samarium.

### Summary.

The relative rates of hydrolysis of 12 rare earth carbonates have been determined.

Lanthanum and cerium<sup>III</sup> showed an abnormal behavior, for which no explanation can now be offered.

Yttrium has been assigned a position in the order of basicity which agrees with the solubilities of its compounds. Previous determinations of its basicity have not done this.

Additional evidence on the serial order of samarium, europium and gadolinium has been offered.

Omitting lanthanum and cerium<sup>III</sup> for the present, the other ten elements investigated are placed in the following order: Pr, Nd, Sm, Eu, Gd, Tb, Dy, Y, Tm, Yb.

## THE JOULE-THOMSON EFFECT FOR AIR.

By FREDERICK G. KEYES.

Received February 17, 1921.

There has recently been completed by L. G. Hoxton<sup>1</sup> a very painstaking experimental investigation of the Joule-Thomson effect in the case of air. In this investigation the effect was measured at several pressures and temperatures, use being made of the experimental values obtained to compute the position of the ice point on the absolute-temperature scale, as well as the constant-pressure air-thermometer-scale corrections to reduce gas-scale readings to the absolute scale. From the temperature coefficient of the Joule-Thomson effect the pressure coefficient of the specific heat for air was computed and compared with the experimental value found by Holborn and Jacobs.<sup>2</sup>

For the absolute temperature of the ice point 273.36 was obtained, while the constant-pressure air-thermometer corrections were in agreement with the mean of the corrections arrived at by Rose-Innes, Callendar, Berthelot, and Buckingham for the nitrogen thermometer. The pressure coefficient of the constant-pressure specific heat for air computed from the temperature coefficient of the Joule-Thomson effect is moreover in good agreement with the first pressure coefficient of Holborn and Jacobs' empirical equation based on their experimental values.

The attention given to possible sources of error and in fact to all details of the experimental procedure by Hoxton is such as to make the work a most important contribution to the experimental study of the Joule-Thomson coefficient. The values obtained, nevertheless, are higher than those obtained by previous workers as noted by Hoxton, and, in consequence, lead to a higher value of the ice point (273.36) than that arrived at by other methods. Hoxton indeed calls attention to the fact that in general the use of the Joule-Thomson effect in computing this constant has, in the calculations of everyone, led to a high value. Thus Buckingham<sup>3</sup> found for the absolute ice-point temperature, making use of the respective Joule-Thomson effects, for air 273.273, for nitrogen 273.286, for carbon dioxide 273.267, while in the case of hydrogen 273.049 was obtained. Berthelot,<sup>4</sup> however, making use of a method of computation based on his equation of state concluded that 273.09 was the correct ice-point temperature, and recently there were presented the results of some calculations by means

<sup>1</sup> Hoxton, *Phys. Rev.*, **13**, 438 (1919).

of my<sup>5</sup> equation of state, applied to nitrogen, hydrogen and helium in the case of both the constant-pressure and constant-volume gas thermometers, which lead to a value somewhat higher (273.14) than Berthelot gives.

In the procedure wherein use is made of the Joule-Thomson coefficients as well as in the equation of state method of arriving at the ice-point temperature, the experimentally determined constant-pressure and constant-volume coefficients of volume and pressure increase between the melting and boiling points of water must be employed. Evidently, if these coefficients were in error, the error would be carried through into the values obtained for the ice-point temperature, and, indeed, high accuracy is demanded since to obtain an accuracy of  $0.1^\circ$  in the ice-point temperature requires that the coefficients should be known to about 1 part in 27000. On the other hand, for this degree of correctness, in the case of air, it is sufficient to have approximately 1% accuracy in the Joule-Thomson coefficient which is involved in the correction term applied to the expansion coefficient.

Apropos of the extreme accuracy with which the expansion coefficient must be known, it is of interest to call attention to the importance in precise measurements of the adsorptive effect of the container walls. The discrepancies in the coefficients of expansion as measured by the same and by different observers may well be assigned to surface adsorptive effects on the inner surface of the thermometer bulb; not perhaps in general to adsorption of the gas on the envelope surface directly but to adsorption or absorption by the water layer which always attaches tenaciously to surfaces.<sup>6</sup> For example, Eumorphopoulos,<sup>7</sup> employing a quartz thermometer bulb with the Callendar compensating type of instrument, after cleaning the bulb with nitric acid and mixed chromic and sulfuric acids, washing repeatedly with distilled water, drying and heating to  $500^\circ$  under exhaustion, found that pure nitrogen dried by phosphoric acid admitted and re-exhausted several times, gave the coefficient of volume increase per degree per cc.  $3.671 \times 10^{-3}$  at 760 mm. Heating and loading as before reduced the value to  $3.6701 \times 10^{-3}$ . It would appear then that the difficulty of extracting adsorbed material from the walls is great even in quartz, and in fact, the gas expansion values of other observers, notably those coefficients measured in glass thermometer bulbs, are invariably high,<sup>8</sup> as compared to values obtained in metal bulbs.

<sup>5</sup> Keyes, *Proc. Nat. Acad. Sci.*, 3, 323 (1917). This equation is:  $p = RT/(v - \delta) - A/(v - l)^2$ , where  $\ln \delta = \ln \beta - \alpha/v$ .

<sup>6</sup> See also for example, concerning the weight of a liter of ammonia: "Thermodynamic Properties of Ammonia," Keyes and Brownlee, p. 216, Wiley and Sons, 1916.

<sup>7</sup> Eumorphopoulos, *Proc. Roy. Soc.*, 90A, 189 (1914).

<sup>8</sup> Holborn and Henning, *Ann. Physik.*, 35, 766 (1911). They obtained for nitrogen in 59<sup>III</sup> glass  $3.6703 \times 10^{-3}$  at 620 mm., but in quartz  $3.6684 \times 10^{-3}$ .

The purpose of the present paper is to give the results of some calculations of the Joule-Thomson coefficients based on the use of my equation of state.<sup>5</sup> The equation of nitrogen for example, has been shown to give the Amagat pressures to about 1000 atmospheres with great exactness over a range of 200°. In the case of air, as will be shown below, the pressures given by Amagat are also in good agreement as well as are the pressures given by other observers at temperatures as low as -130°, although in the latter case not high pressures for reasons which can be more appropriately discussed in another paper. It is conceivable, however, that an equation of state might serve to calculate pressures over a comparatively limited temperature range to a very satisfactory degree and still be defective in form, and in consequence lead to erroneous values for the derived quantities, such as, for example,  $\left(\frac{\partial v}{\partial T}\right)_p$  and  $\left(\frac{\partial p}{\partial T}\right)_v$  which are involved in calculating the Joule-Thomson coefficients.

The form of function has, however, been tested by comparing the term (corresponding to van der Waals'  $b$ ) and  $\phi$  the cohesive pressure term separately at high pressures over a temperature range extending 100° on each side of the fixed points (0° and 100°) under discussion in the present paper. The functional forms for  $\delta$  and  $\phi$  in the equation have been shown to be exact, and at low pressures should give accordingly the derived quantities with great precision.

To give a survey of the degree of exactness with which the equation of state for air accords with the measurements, there are presented in Tables I, II and III the data of Amagat<sup>9</sup> upon which the constants of the equation are based, those of Witkowski<sup>10</sup> and finally, the recent pressure volume and temperature observations for air by Holborn and Schultz.<sup>11</sup>

The agreement of the calculated and observed pressures is not perhaps as good as in the case of nitrogen because the oxygen of the air in Amagat's work might have reacted to some extent with the mercury used to confine it at higher temperatures and pressures. Each observer's data are, however, well represented, and the equation is, therefore, concluded to be exact from -130 to 200° over a wide pressure range.<sup>12</sup>

<sup>9</sup> Amagat, *Ann. chim. phys.*, 29, 52 (1893).

<sup>10</sup> Witkowski, *Bull. Acad. Cracovie*, 1891, 181; or *Phil. Mag.*, 41, 288 (1896).

<sup>11</sup> Holborn and Schultz, *Ann. Physik.*, 47, 1089 (1915).

<sup>12</sup> It has been suggested that any equation of state containing four constants should represent the data. The habit of regarding an equation as simply one containing a number of arbitrary constants which will represent the data with better accuracy as the number of constants is increased is certainly common enough, but not particularly adequate. In the case of an equation of state, there is a relation between three variables, and the form of the function becomes of more importance than the mere number of constants.

There are examples enough in the literature of equations having many constants

$$p = \frac{2.833}{v - \delta} T - \frac{A}{(v - l)^2}, \text{ where } \log_{10} \delta = 0.20113 - \frac{0.296}{v} \quad A = 1605.3; l = -0.088.$$

Having shown that the pressures for air are given by the equation over a wide range of pressure, volume and temperature, the Joule-Thomson coefficients calculated from the equation are valuable as a standard of reference from which to discuss the experimental values. Moreover, by means of a comparison of calculated and experimental values, some light will be thrown upon the magnitude of the possible errors affecting the expansion coefficients and the Joule-Thomson numbers, thus assisting in extending the accuracy with which these important constants can be measured.

A peculiarity of the particular equation<sup>13</sup> of state for air, so far above its critical temperature, is that the pressure at constant volume is a linear and still failing to represent the pressure, volume and temperature data as accurately as desirable. In a recent article (THIS JOURNAL, 41, 591 (1919)), I have gone into this matter at some length to make clear the importance of the form of function, and in the article referred to special measurements were made to test the functional form, and further data are being obtained with improved apparatus.

<sup>13</sup> In a previous paper (THIS JOURNAL, 41, 589 (1919)), it has been shown that the equation in the simple form is particular in that it applies to a system whose molecules remain of invariable species in a given phase. That is to say, there is assumed to be no association, which at so many degrees above the critical point is true enough for the so-called permanent gases. It is only for a one-type molecular assemblage that the linear increase of pressure with temperatures at constant volume is conceivable. Indeed, for such a system, any other manner of pressure increase appears illogical unless we are

function of the temperature. In the region of the critical temperature and of small volumes (10 cc. per g.), this is no longer true. The linear increase of pressure with temperature at constant volume requires as a thermodynamic consequence that the constant-volume specific heat shall be independent of the volume. The constant-pressure specific heat  $C_p$  will, therefore, follow from the thermodynamic equation  $C_p =$

$C_v + T \left( \frac{\partial v}{\partial T} \right)_p \left( \frac{\partial p}{\partial T} \right)_v$  on applying the equation to compute the expression for the second term of the right-hand member. There is obtained from

$$\left( \frac{\partial p}{\partial T} \right)_v = \frac{R}{v - \delta} \quad \text{and} \quad \left( \frac{\partial v}{\partial T} \right)_p = \frac{v - \delta}{T} \times \frac{1 - \frac{\alpha \delta}{v^2} - \frac{2A}{RT} \frac{(v - \delta)^2}{(v - l)^3}}{1 - \frac{\alpha \delta}{v^2} - \frac{2A}{RT} \frac{(v - \delta)^2}{(v - l)^3}}$$

and the air constants, the following equation,

$$C_p = C_v + \frac{R}{1 - \frac{\alpha \delta}{v^2} - \frac{2A}{RT} \frac{(v - \delta)^2}{(v - l)^3}} = \left[ 0.241 + 2.5 \times 10^{-4} p \right]_{58^\circ} \text{approximately.}$$

Holborn and Jacobs<sup>14</sup> find  $2.86 \times 10^{-4}$  for the pressure coefficient in their equation  $C_p = 0.2413 + 2.86 \times 10^{-4} p + 5.0 \times 10^{-8} p^2 - 1.0 \times 10^{-9} p^3$ . At 200 atmospheres the calculated specific heat is 0.291 as compared with Holborn and Jacobs' 0.2925 from the equation representing their measurements.

The thermodynamic equation of the Joule-Thomson effect is  $\frac{dT}{dp} =$

$$\mu = - \frac{T \left( \frac{\partial v}{\partial T} \right)_p - v}{C_p} \quad \text{and the equation of state gives then}$$

$$\frac{\frac{2A}{RT} \frac{(v - \delta)^2}{(v - l)^3} v - \delta \left( 1 - \frac{\alpha}{v} \right)}{C_v \left( 1 - \frac{\alpha \delta}{v^2} - \frac{2A}{RT} \frac{(v - \delta)^2}{(v - l)^3} \right) + R}$$

willing to accept that temperature can influence the residual electro-magnetic fields which are the assumed cause of the mutual attraction between the molecules composing the fluid, and such a temperature effect has not been established so far as known.

<sup>14</sup> The coefficients to the higher powers have been omitted since the first pressure coefficient of Holborn and Jacobs' empirical equation is the most accurate. In the equation given, the  $p$  coefficient is taken as  $R \times \frac{2A}{R^2 T^2}$  being the first approximation of

$$\frac{R}{1 - \frac{\alpha \delta}{v^2} - \frac{2A}{RT} \frac{(v - \delta)^2}{(v - l)^3}} \quad \text{it being assumed that the specific heat at one atmosphere is } C_p + R = 0.238.$$

The equation given is complete, but for the low pressures that are here to be considered, it suffices to make the following reductions. For  $\frac{(v-\delta)^2 v}{(v-l)^3}$ , may be written  $\left(1 - \frac{2\beta}{RT} p\right)$ ; for  $\delta \left(1 - \frac{\alpha}{v}\right)$ ,  $\beta \left(1 - \frac{2\alpha}{RT} p\right)$ ; and for  $\frac{(v-\delta)^2}{(v-l)^3} \frac{p}{RT}$ .

There results then the equation

$$\mu_p = \mu_0 + \left[ \mu_0 \frac{C_p}{C_{p_0}} \frac{2A}{R^2 T^2} - \frac{4A\beta}{C_{p_0} R^2 T^2} + \frac{2\alpha\beta}{C_{p_0} RT} \right] p.$$

where  $\mu_0$  represents the quantity  $\left(\frac{2A}{RT} - \beta\right)/C_{p_0}$ , the Joule-Thomson effect at infinitely low pressure, and  $C_{p_0} = C_p + R$ , the constant-pressure specific heat at infinitely low pressures. It will be observed that the pressure coefficient can be positive or negative depending upon the temperature, although it is to be observed that the coefficient of  $p$  is the tangent to the  $\mu, p$  curve at the  $\mu$  axis only.

TABLE IV.  
Experimental and Computed Joule-Thomson Coefficients for Air.

$t$	Calculated.	J. and T. Buckingham.	Noell.	Hoxton.			
	1 atm.	1 to 6 atm.	Corr. states.	1 to 3 atm.	1.3 atm.	3.4 atm.	4.9 atm.
0°	0.2615	0.275	0.284	0.277	0.303	0.284	0.272
50°	0.1957	0.197	0.205	0.185	0.226	0.211	0.205
100°	0.1477	0.147	0.161	0.125	0.170	0.160	0.154

The temperature coefficient may be positive or negative depending on the temperature. The effect itself ( $\mu$ ) is zero at low pressures when  $T = \frac{2A}{R\beta}$ , but the temperature of inversion diminishes as the pressure increases at high pressures.

Substituting the numerical values of the constants given under Table I, there results the following equation,  $\mu_0 = \frac{115.8}{T} - 0.1625$  where  $C_{p_0} = 0.238$  is assumed constant. The pressure coefficient is at 0°;  $-4.7 \times 10^{-4}$  and at  $-100$ ;  $+9.2 \times 10^{-4}$  for low pressures. The mean pressure coefficient 0 to 200 atmospheres is  $7.1 \times 10^{-4}$  at zero degrees.

Table IV gives a survey of the experimental values together with those computed by the equation. It is perceived that the values of the effect obtained by Hoxton at the higher pressures are not far from those obtained by Joule and Thomson. The Joule and Thomson numbers were obtained by expanding from about 6 atmospheres down to 1 atmosphere, and, therefore, represent the integrated effect over the pressure drop.

The differences in the various values are, however, so great and the pressure effect so small ( $-4.7 \times 10^{-5}$  per atmosphere calculated for low pressures) that for the accuracy attained it is futile to take into account whether the pressure amounted to one or several atmospheres. It is to be noted, however, that Hoxton has observed a large pressure effect experimentally amounting to  $5.6 \times 10^{-3}$  or the order of ten times the calculated value ( $4.7 \times 10^{-4}$ ). Vogel's<sup>15</sup> pressure coefficient ( $8.6 \times 10^{-4}$ ) is lower than Hoxton's, but somewhat larger than that calculated, while Dalton<sup>16</sup> working in Onnes' laboratory finds  $6.0 \times 10^{-4}$ . Bradley and Hale,<sup>17</sup> however, made a series of measurements at temperatures from 0 to  $-110^\circ$  expanding through pressure differences of 68, 102, 136, 170 and 204 atmospheres to one atmosphere, thereby obtaining the integral Joule-Thomson effect.

Bradley and Hale measured the fall in temperature attending the throttling of air from 68, 75, 101, 150 and 204 atmospheres to one atmosphere when the gas on the high pressure side of the plug was maintained at a series of different temperatures. By plotting the pressures with the attendant temperature drops, a series of curves was described, one for each initial temperature. The tangent at any point on the curves is the value of  $dt/dt$  the Joule-Thomson coefficient. From the curves of Bradley and Hale's data the values at the pressures of 50, 100, 150 and 200 atmospheres were read. Each of these constant-pressure series of values was then plotted with the reciprocal of the corresponding absolute temperature, which permitted the value of  $\mu$  at the ice point to be read corresponding to each constant pressure. These ice-point temperature values are:  $\mu = 0.2330$  at 50 atmospheres,  $\mu = 0.1915$  at 100 atmospheres,  $\mu = 0.1615$  at 150 atmospheres, and  $\mu = 0.1166$  at 200 atmospheres. The values are related to the pressure with sufficient exactness for the present purpose by the equation  $\mu = 0.268 - 7.3 \times 10^{-4}p$ . This equation gives for  $\mu$  at 50 atmospheres 0.232, at 100 atmospheres 0.194, at 150 atmospheres 0.158, at 200 atmospheres 0.121. At  $0^\circ$ , therefore, Bradley and Hale's work indicates that the pressure coefficient of the Joule-Thomson effect is  $-7.3 \times 10^{-4}$ . The complete equation for the effect at zero degrees derived from the equation of state gives at 200 atmospheres 0.1196 while the one atmosphere value is 0.261. The average coefficient is therefore  $7.1 \times 10^{-4}$  which agrees very well with the Bradley and Hale value.<sup>17</sup> At low pressures the pressure coefficient is the order of  $5 \times 10^{-4}$ , so that the numerical value of the coefficient increases slowly with pressure. It appears, therefore, that the pressure coefficient as found by Hoxton is the order of 8-fold too large.

### The Expansion Coefficients of a Gas.

The computation of the expression giving the constant-pressure expansion coefficient may be readily obtained from the equation of state. For the large volumes which are here in question, it suffices to assume

$\delta = \beta$  and to neglect  $l$  in the cohesive pressure term  $\phi = \frac{A}{(v-l)^2}$ . The

equation assumes the form, therefore,  $p = \frac{R}{v-\beta} T - \frac{A}{v^2}$  for low pressure

analogous in form to the van der Waals equation. Setting  $p + \frac{A}{v^2} = \pi$

and  $(v - \beta) = \omega$  the equation of an actual gas at not too small volumes becomes  $\pi\omega = RT$  identical in form with the perfect gas equation. If  $\pi$  can be kept constant, therefore, the absolute centigrade temperatures will be given by the expression

$$t_a = \left[ \frac{\omega_t - \omega_o}{\omega \epsilon} \right]_{\pi} \quad (1)$$

where  $\epsilon$  is the expansion coefficient of a perfect gas. The quantity  $\omega_o$  will always be invariable in magnitude in a given apparatus filling, but  $\omega_t$  must be always taken with  $\pi$  or  $(p_1 + \phi_1)$  constant. Since, however, the volume is increasing with temperature rise,  $\phi$  will diminish progressively, and since  $(p_o + \phi_o)$  must always equal  $(p_1 + \phi_1)$ , where the zero subscripts refer to the ice-point values of the quantities designated and the numeral to the value of the quantities at any temperature, it is clear that

$p_1 > p_o$  and  $p_1 - p_o = \phi_o - \phi_1 = A \left( \frac{1}{v_o^2} - \frac{1}{v_1^2} \right)$  will therefore always remain

a positive quantity. If further  $\omega'$  is taken to represent the value of  $(v_1 - \beta)$  at the constant initial pressure  $p_o$  according to the usual constant pressure thermometer procedure,  $\omega_1$  will be given by multiplying  $\omega'_1$  by

the ratio  $\frac{p_o}{p_1}$ . Substituting then in Equation 1 there results,

$$\frac{\omega'_1 \frac{p_o}{p_1}}{\omega_o t_a} = \epsilon = \frac{\frac{v_1 - v_o}{v_o t} - \left( \frac{v'_1 - \beta}{v_o t} - \frac{\beta}{v_o t} \right) \left( 1 - \frac{p_o}{p_1} \right)}{\left( 1 - \frac{\beta}{v_o} \right) \frac{t_a}{t}} \quad (2)$$

At  $100^\circ$   $t_a = t$  and  $\frac{v'_1 - v_o}{v_o t} = \epsilon_p$  the expansion coefficient of the gas under

measurement. The value of  $\left( 1 - \frac{p_o}{p_1} \right)$  may be obtained in terms of the con-

stants of the equation, for since  $p_1 - p_o = \phi_o - \phi_1$ ;  $\left( 1 - \frac{p_o}{p_1} \right)$  may be taken

equivalent to  $\frac{A}{p_0} \left( \frac{1}{v_0^2} - \frac{1}{v_1^2} \right)$  or  $\frac{A \epsilon_p t}{R^2 T_0^2} \left( \frac{2 + \epsilon_p t}{1 + \epsilon_p t} \right) p_0$  assuming  $p v = R T$  for  $v_0$  and  $v_1$ . The equation for  $\epsilon_p$  may now be reduced to the following equation

$$\epsilon_p = \epsilon + \left[ \epsilon_p \frac{A(2 + \epsilon t)}{R^2 T_0^2 (1 + \epsilon t)} - \frac{\beta}{R T_0^2} \right] p_0 - \left[ \frac{A \beta \epsilon_p (2 + \epsilon t)}{R^3 T_0^3 (1 + \epsilon t)^2} \right] p_0^2. \quad (3)$$

Using 1 mm. of mercury as the unit of pressure, substitution of the numerical values of the constants for air gives the following equation for the mean constant-pressure expansion coefficient between  $0^\circ$  and  $100^\circ$  assuming  $\epsilon$  as the reciprocal of 273.135,

$$\epsilon_p = 0.00366119 + 12.45 \times 10^{-9} p_0 - 4.43 \times 10^{-14} p_0^2. \quad (4)$$

It is to be observed that the constant-pressure coefficient is a function of the temperature interval within which the expansion is measured since the coefficients of  $p_0$  and  $p_0^2$  in Equation 3 are a temperature function.

The formula for the constant volume coefficient is more simply obtained. Proceeding as before

$$\left[ \frac{\pi_1 - \pi_0}{\pi_0 t} \right]_v \quad (p_0 + \phi_0) t$$

Constant  $\omega$  is identical with constant volume and therefore  $\phi_1 = \phi_0$  at all temperatures is constant.  $\frac{p_1 - p_0}{p_0 t}$  is defined as  $\epsilon_v$  the constant volume coefficient of the actual gas and consequently

$$\epsilon_v = \epsilon + \epsilon \frac{\phi_0}{p_0} = \epsilon + \frac{A}{R^2 T_0^2} p_0. \quad (5)$$

The numerical values of the constants for air give the following equation where the pressure unit is mm.,

$$\epsilon_v = 0.00366119 + 12.93 \times 10^{-9} p_0. \quad (6)$$

It is to be noted that the pressure coefficient is independent of the temperature.

### The Absolute Ice-Point Temperature.

The thermodynamic equation for the Joule-Thomson effect may be written as follows,

$$\mu c_p = T^2 \frac{\partial \frac{v}{T}}{\partial T}. \quad (7)$$

Integration of this equation leads to the equation of the constant pressure gas thermometer

$$\frac{v}{T} - \frac{v_o}{T_o} = c_p \int_{T_o}^T \frac{\mu}{T^2} dT = J_o^{100}. \quad (8)$$

The expansion coefficient  $\epsilon_p$  is defined through the equation  $v_{100} = v_o(1 + \epsilon_p 100)$  and for the fixed points  $0^\circ$  and  $100^\circ$ , Equation 8 may be re-arranged to give  $T_o$ , the absolute temperature of the ice point.

$$T_o = \frac{1}{\epsilon_p - \frac{T_{100}}{v_o 100} J_o^{100}}.$$

The integration of the Joule-Thomson effect member may be made by using the value of  $\mu$  formed from the equation of state and is as follows.

$$c_p \int_0^{100} \frac{\mu}{T^2} dT = \frac{2A}{R} \int_0^{100} \frac{dT}{T^3} - \beta \int_0^{100} \frac{dT}{T^2} = 1.963 \times 10^{-3}.$$

The ice-point temperature becomes then where the pressure is in mm.,

$$T_o = \frac{1}{\epsilon_p - 12.46 \times 10^{-3} \beta}.$$

Using the values of the expansion coefficients at constant pressure given in Table V gives the values of  $T_o$  appearing in Table VI.

TABLE VI.

760	3.67063	Calc.	272.431	273.135	Calc.

It is evident that Regnault's value at 760 mm. and Chappuis' at 1000 mm. for the expansion coefficient are different when reduced to the same

pressure, by about 1 part in 4500, but also that the value of  $T_0$  from Regnault's coefficient (760 mm.) is more nearly in accord with the probable values of  $T_0$ , which latter is certainly not lower than 273.1 nor greater than 273.15. The 2525 mm. observation of Regnault is not sufficiently exact (1 part in 1700) for the present purpose for at such a pressure the distortion of the thermometer bulb by pressure becomes a serious factor.

The values of  $T_0$  derived from the measured values of  $\epsilon_p$  and  $\epsilon_v$  for nitrogen, hydrogen and helium have been given in a previous paper<sup>18</sup> and in the method of calculation employed, use was made of the pressure coefficients alone derived from the equation of state for the respective gases. In this method of computing  $T_0$  in no case does  $T_0$  come out greater than 273.153 while the most trustworthy expansion coefficients ( $\epsilon_v$ ) measured by Day and Clement, ranging in initial pressure from 314 mm. to 985 mm. give 273.133, 273.128, 273.147 and 273.139 or a mean value of 273.137. The expansion coefficients of the gases referred to lead to values of  $T_0$  which indicate therefore that Chappuis'  $\epsilon_p$  value of air at 1000 mm. is too small. The hydrogen  $\epsilon_v$  and  $\epsilon_p$  values of Chappuis, indeed, give by the same method of calculation  $T_0 = 273.147$ , and 273.115, respectively.

The conclusion appears inevitable, therefore, that the ice-point temperature as calculated from the Chappuis 1000 mm. value is too large because the latter value is too small by about one part in 4700 and the experimental values of  $\mu$  correlated as a function of the temperature to correct the  $\epsilon_p$  value are too large. The last horizontal entry in Table VI shows that the  $\mu$  equation derived from the equation of state gives with the calculated value of  $\epsilon_p$  an ice-point temperature (273.135) in accord with values of this constant obtained by other methods from the data on several gases.

If this value ( $T_0 = 273.135$ ) is accepted there is thus no escape from the conclusion that Chappuis' 1000 mm.  $\epsilon_p$  value for air is in error and at all events inconsistent with  $T_0$  deduced from his values obtained for other gases.

There is, however, still another method which may be used to obtain  $T_0$  which is independent of any equation of state. This consists simply of plotting the values of  $\epsilon_p$  and  $\epsilon_v$  with the corresponding pressures and finding where the most representative line cuts the  $\epsilon$  axis. Such a plot is given in Fig. 1 wherein there have been drawn the lines for  $\epsilon_p$  and  $\epsilon_v$  derived from the respective equations of state as a function of the pressure for the several gases; and the dimensions of the original chart are such that 1 mm. indicates 1 part in 90,000 for  $\epsilon$ . The most numerous and usable data are those for nitrogen; the series of Chappuis'  $\epsilon_v$  values are higher than those of Day and Clement, but, nevertheless, the representative line for Chappuis' data cuts the  $\epsilon$  axis at about  $3.66132 \times 10^{-3}$  giving

<sup>18</sup> THIS JOURNAL, 42, 54 (1920).

$T_0 = 273.126$ . The Day and Clement values are clearly represented by the line resulting from the equation of state, and accordingly  $T_0$  would be about 273.14. The constant-pressure values for nitrogen due to Eumorphopoulos obtained with the use of a quartz-bulb thermometer lead by extrapolation to  $T_0 = 273.147$ . The mean of all three values is close to 273.135. It will be noted in addition that the pressure coefficients

Fig. 1.

for  $\epsilon_p$  and  $\epsilon_p$  in the case of hydrogen are nearly equal numerically, but of opposite sign. The mean value of the two coefficients should be close to  $\frac{1}{T_0}$  and, in fact, amounts to  $3.366123 \times 10^{-3}$  whose reciprocal is 273.128.

Helium<sup>8</sup> is so nearly an ideal gas that almost any equation of state which approximately represents the isotherms should suffice. The equation which I have obtained based on the work of the Onnes laboratory leads to  $T_0 = 273.113$ . The mean of the graphically extrapolated  $\epsilon_p$  and  $\epsilon_p$  values then of Chappuis'  $\epsilon_p$  nitrogen values, Eumorphopoulos'  $\epsilon_p$  nitrogen values, Day and Clement's  $\epsilon_p$  nitrogen values is 273.137. Including the single helium  $\epsilon_p$  value of Holborn and Henning, the mean  $T_0$  amounts to 273.131.

It appears clear that  $T_0$  must be taken as very nearly 273.13 and the probability is that it does not exceed 273.14 in value, while Berthelot's value, 273.09, is judged therefore to be too low. With  $T_0$  assured, the conclusion is inevitable that all the measured Joule-Thomson numbers

are too large. A study of the original Joule-Thomson papers and all of the later communications offers no certain clue as to the probable reason for obtaining too large numbers, but if heat leaks or radiation effects of all kinds as well as "velocity cooling" disturbances may be assumed disposed of, there remain only two conceivable methods of changing the temperature of an isolated quantity of gas, in the sense that the internal energy change shall be equal to the energy element either  $p dv$  or  $d(pv)$ . In the former case, the temperature change produced per atmosphere at one atmosphere is about  $70^\circ$ , whereas in the latter it does not much exceed  $0.25^\circ$ .

The fine pores of the plug offer a resistance to the passage of the gas such as to maintain the pressure difference and it issues from the low-pressure face of the plug in fine streams of high velocity which presumably persist momentarily. There could be, therefore, local differences in density which result in further expansion against the gas on the low pressure side. It is in this region that a lower temperature results and only at a considerable distance from the plug would density and temperature differences be inappreciable. Unfortunately there is great difficulty in avoiding other sources of error such as heat conductance or radiation at a distance from the plug. It was noticed that the pressure coefficient observed by Hoxton is larger and this is the trend the measurements would take since the temperature change for the fine stream-persistence

suggested above is given by the equation  $\frac{dT}{dp} = T \frac{\left(\frac{\partial \eta}{\partial T}\right)_2}{C_p} \equiv \frac{RT}{p} \cdot \frac{1}{C_p}$  when  $p\eta = RT$ .

That is to say the effect of finite density differences expressed as a temperature change of this kind would be less at higher pressures. Thus there would result an apparent pressure coefficient much too large; furthermore, Joule-Thomson measurements made with high pressure differences would be more reliable than those with small pressure differences as is evident in the work of Bradley and Hale.

It is difficult to infer much from the work of Joule and Thomson on other gases than air, since in no case were the gases sufficiently pure to warrant great confidence in the numbers obtained. It is true in the case of nitrogen, oxygen, hydrogen and carbon dioxide, the attempt was made to correct for the impurities, but the relation between the Joule-Thomson effect in a given mixture and the Joule-Thomson effects in the constituents was then, as now, entirely unknown.

An examination of all the Joule-Thomson data available shows that the effect as related to temperature can be adequately represented within the limits of experimental error as a linear function of the inverse abso-

lute temperature as indicated in Fig. 2. This is clearly brought out by comparing the data plotted to different powers of the reciprocal absolute temperature. If the temperature function is linear in the reciprocal absolute temperature, there are no corrections required for the constant volume temperature scale,<sup>19</sup> supporting the form of the equation of state which adequately represents the pressures observed over such a wide range of both pressure and temperature. In any event, a very accurate means of establishing the linearity of the pressure increase with temperature at constant volume does lie in obtaining accurate measurements of the Joule-Thomson coefficients at various temperatures and low pressures (1 to 5 atmospheres) although the experimental difficulties are considerable.

Fig. 2.

There is, however, one other method of attack bearing on the temperature function of the Joule-Thomson coefficient which consists of measuring the constant-volume specific heat at increasing pressures. Joly's data for air appear to indicate an increase of  $C_v$  with pressure, but an examination of his data for this gas leaves one entirely unconvinced regarding the dependence of the constant-volume specific heat on pressure. It becomes, in fact, a conviction that  $C_v$  is indeed constant from the data given when correction is made for the change in heat capacity of the copper sphere used due to the tension in the copper caused by the pressure of air within, for the compensating sphere on the opposite scale pan was exhausted. An attempt to make this correction follows.

<sup>19</sup> The calculated corrections for the constant-pressure scale from the equation of state for air follow easily from Equation 2 and accord well with the nitrogen scale corrections although several thousandths of a degree smaller than those calculated by Hoxton.

### The Joly Constant-Volume Specific-Heat Values for Air.

Joly presents seven measurements in the case of air at pressures varying from about 7 atmospheres to about 27 atmospheres. The copper spheres weighed 92.4 gr. and had a capacity of 159.8 cc. at  $15^{\circ}$ . There was, therefore, in each sphere 10.36 cc. of copper and the internal and external radii were respectively 3.3660 and 3.4373 cm. with a wall thickness of 0.0713 cm. Considering a patch on the surface of the sphere, it is perceived to be stretched under the internal pressure in two dimensions while the stresses along the radius will be neglected. Considering the thickness moreover as insignificant in comparison with the radius the tension on the copper section of a great circle due to the pressure of one atmosphere on a great area will be 24 atmospheres per cc. of copper. Consider then that each cubic centimeter of the copper has applied to its 4 faces intersected by a plane a uniform pull outward of 24 atmospheres for each atmosphere of gaseous pressure within the actual copper sphere. Assume further that a uniform pull of  $\frac{2}{3} \times 24 = 16$  atmospheres uniform tension on each face of the cubic centimeter will represent with sufficient approximation the actual state of tension in the copper sphere.

The change of specific heat with pressure is given by the equation,

$$\left(\frac{\partial C_p}{\partial p}\right)_T = -T \left(\frac{\partial^2 v}{\partial T^2}\right)_p.$$

This equation is to be applied to the case of a tension in the material and  $\left(\frac{\partial^2 v}{\partial T^2}\right)_p$  assumed constant. Designating the specific heat of copper at zero tension as  $C_{p0}$  there is obtained for the difference of the specific heats at any tension  $p$ ,

$$C_p - C_{p0} = \left(\frac{\partial^2 v}{\partial T^2}\right)_p p.$$

Since the compensating sphere was exhausted it is unnecessary to subtract 1 from  $p$  to take account of the fact that the surrounding pressure was that of the atmosphere.

From Henning's recent work on the expansion of copper from  $-191^{\circ}$  to  $500^{\circ}$  the following equation was formulated giving the true expansion at every temperature  $T$ ,

$$\frac{1}{v_0} \frac{\partial v}{\partial T} = 31.94 \times 10^{-6} + 6.347 \times 10^{-8} T - 3.7 \times 10^{-11} T^2, \text{ and}$$

$$\frac{1}{v_0} \frac{\partial^2 v}{\partial T^2} = 6.35 \times 10^{-8} - 7.4 \times 10^{-11} T.$$

The numerical equation for the difference of the specific heats becomes for the 10.36 cc. of copper composing the sphere in calories per degree per atmosphere tension

$$C_p - C_{p0} = 5.07 \times 10^{-5} p$$

Joly's equation of the specific heat of air at constant volume is given as  $C_v = 0.17151 + 0.02788 \times \text{density}$ . The same equation in which the pressure is the variable instead of the density is  $C_v = 0.17151 + 3.3 \times 10^{-5} p$ . The coefficient of the increase of the specific heat of the copper sphere used to contain the gas is as has been shown to be  $5.07 \times 10^{-5}$  a number which is of the order of magnitude of Joly's coefficient  $3.3 \times 10^{-5}$ .

The actual experimental values are given in the order of pressure increase in the first column of Table VII. The third column gives the

TABLE VII.

Mean value 0.17121

correction corresponding to the pressure given in the second column as calculated by means of the specific-heat difference equation above for the copper sphere, while the fourth column contains the final specific-heat values whose mean is 0.1712. The last column contains the deviations from the mean value 0.1712. It is evident that the constant-volume specific heat of air is independent of pressure over the range of about 27 atmospheres at least.

The equation for the change of the constant-volume specific heat with volume is

$$\left( \frac{\partial C_v}{\partial v} \right)_T = T \left( \frac{\partial^2 p}{\partial T^2} \right)_v.$$

The left hand member is zero as shown by the measurements of Joly and hence  $\left( \frac{\partial^2 p}{\partial T^2} \right)_v = 0$  or  $\left( \frac{\partial p}{\partial T} \right)_v = \text{const.}$  which when integrated again gives  $[p]_v = \text{const.} \times T + \text{another constant.}$  The pressure is therefore a linear function of the temperature and at low pressures the Joule-Thomson effect must vary with respect to temperature linearly with the

inverse of the absolute temperature. This is also, as stated above, the conclusion from the data on the volume, pressure and temperature of air as given by my equation. The experimental data, in fact, of the Joule-Thomson effect at not too high pressures are represented by an equation of the form  $\mu = \frac{a}{T} - b$  as is indicated by Fig. 2.

The Joly data indicating independence of pressure of the constant-volume specific heat indicate also of course that the constant-volume air thermometer reads directly on the absolute scale and requires no correction. While explicit experimental confirmation is not as complete in the case of nitrogen, upon which our temperature scale rests, the same statement applies.<sup>18</sup>

### Summary.

1. The Joule-Thomson coefficients of air have been calculated from my equation of state for air based on the measurements of pressure, volume and temperature by Amagat, and have been compared with the coefficients as measured by Joule and Thomson, Noell and Hoxton. The measurements of Joule and Thomson accord well with the calculations except at zero degrees, while the recent careful measurements of Hoxton exceed the calculated values between 0 and 100° by about 15%.

2. The value of the ice-point absolute temperature (273.36) deduced from the Chappuis 1000 mm. constant-pressure expansion coefficient for air corrected by means of the Hoxton Joule-Thomson coefficients is too large, due to the fact that the Chappuis expansion coefficient is too small and the Joule-Thomson values too large. The calculated expansion coefficient and the Hoxton Joule-Thomson coefficients lead to  $T_0 = 273.197$ . The value  $T_0 = 273.135$  is on the other hand shown to be substantially correct in that this value is the mean value obtained by graphically extrapolating the measured constant volume and constant-pressure expansion coefficients of air, nitrogen, hydrogen and helium measured at various ice-point pressures. The value 273.135 is also the mean of  $T_0$  as deduced from the same data by means of the equations of state for the respective gases.

3. The pressure coefficient at zero of the Joule-Thomson coefficient as obtained by Hoxton is shown to be much larger than that obtained by other observers. The pressure coefficient given by Vogel and Noell ( $8.8 \times 10^{-4}$ ) is twice that calculated from the equation ( $4.5 \times 10^{-4}$ ) for low pressures, but agrees approximately with that calculated for high pressures, by means of the equation of state. The Bradley and Hale average pressure coefficient to 200 atmospheres at 0° is shown to be  $7.3 \times 10^{-4}$  while the average value over this range computed by the equation of state

is  $7.1 \times 10^{-4}$ . The Joule-Thomson coefficient itself at 1 atmosphere as given by Vogel and Noell is  $0.277^\circ$  and from Bradley's work  $0.268^\circ$ . The equation gives  $0.261^\circ$ .

4. An explanation of the discrepancies in the observed Joule-Thomson numbers is suggested which assumes that at the low-pressure surface of the plug a temperature drop is superposed on the Joule-Thomson temperature change due to the momentary persistence of the fine gas streams issuing from the pores of the plug and their subsequent expansion. It is shown that this effect would produce a large apparent pressure coefficient since the specific effect of the velocity-persistence-effect is shown to vary inversely as the pressure. The value of the measured Joule-Thomson effect at  $0^\circ$  and one atmosphere pressure is given as 0.303 by Hoxton, while that deduced from the high-pressure measurements of Bradley and Hale is 0.268, as compared with 0.261 calculated by the equation of state.

5. The Joly constant-volume specific heats of air are considered, and it is shown that a correction is required to compensate for the increased specific heat of the copper sphere used by Joly to contain the air. The corrected Joly values are shown to be independent of pressure, which fact confirms the validity of the form of the air equation of state employed. As a further consequence, it is pointed out that at low pressures the Joule-Thomson effect must vary inversely with the absolute temperature. Another important consequence is that the constant-volume air-thermometer scale reads directly on the absolute scale and therefore requires no correction.

## COMPOUND FORMATION AND SOLUBILITY IN SYSTEMS OF THE TYPE, FORMIC ACID:METAL FORMATE.

BY JAMES KENDALL AND HOWARD ADLER.

Received February 25, 1921.

The experimental work presented in the following pages has been carried out with the object of determining how far the conclusions arrived at in a similar study of systems of the type sulfuric acid: metal sulfate<sup>1</sup> may be considered as generally valid for systems  $HX : RX$ . In order to make the test as rigorous as possible, a careful selection of an acid diverse in all properties from sulfuric acid was necessary. Formic acid was finally chosen as a typical weak monobasic organic acid, contrasting strikingly with sulfuric acid, a typical strong dibasic inorganic acid. It

<sup>1</sup> Kendall and Landon, *THIS JOURNAL*, 42, 2131 (1920); Kendall and Davidson, *ibid.*, 43, 979 (1921).

is true that a still weaker acid might have been selected to obtain a more extreme contrast, but when it is noted that previous investigations on systems of the type  $\text{ROH} : \text{HOH}$  already furnish us with considerable data for the case of an exceedingly weak acid, the desirability of choosing an example of an intermediate type (such as formic acid) to complete the field becomes obvious. The instability of the formates of the more noble metals prevents a full survey of the series being made, but against this disadvantage is to be placed the convenience of the melting points of formic acid and its derivatives, which facilitates the experimental procedure and allows the various systems to be investigated through much larger concentration ranges than would otherwise be possible.<sup>2</sup> Furthermore, careful determinations of the conductivities of several formates in formic acid have been made by Schlesinger<sup>3</sup> and his co-workers, providing material for the future correlation of the results here obtained with ionization relationships, the final object of this work.<sup>4</sup> Nevertheless, in order that no gaps should be left in the series, a few systems of the type acetic-acid: metal-acetate have also been included in this investigation.

Practically no previous work of value has been done upon acid formates and acetates. Although Groschuff<sup>5</sup> employed the freezing-point method to examine certain of the formates with formic acid, the majority of the results obtained by him are considerably in error. A few acid acetates have been reported in isolated investigations, usually of great age and of doubtful accuracy, but no systematic study such as is here attempted has hitherto been undertaken.

In the present work the following systems have been examined: (a) with formic acid; potassium, ammonium, sodium, lithium, barium, calcium, magnesium, zinc, nickel, lead and copper formates: (b) with acetic acid; sodium, calcium, zinc, ferric and silver acetates.

in a modified Beckmann apparatus, the work at higher temperatures in sealed bulbs.

The more accurate freezing-point tube method could be employed only for temperatures below  $60^{\circ}$ , owing to the volatility of the acids at higher temperatures. In the sealed bulbs the air space was made as small as possible to reduce concentration changes in the solutions due to this cause. Fortunately, secondary disturbing factors such as were met with in the case of the sulfates<sup>7</sup> were here absent, so that the curves could be carried to much higher concentrations of salt than was there found feasible. A limit was set in most cases, however, by the decomposition temperature of the acid or of the neutral salt.<sup>8</sup> Only for potassium and ammonium formates, which are stable beyond their relatively low melting points, could the determinations be extended right through the complete system.

Formic acid was prepared from a standard C. P. product by treatment with boron trioxide for the removal of final traces of water.<sup>9</sup> Distillation *in vacuo* under anhydrous conditions was continued until a product melting at over  $8.4^{\circ}$  was obtained.<sup>10</sup> Acetic acid melting at  $16.5^{\circ}+$  was prepared by addition of acetic anhydride to glacial acid, as described by Kendall and Gross.<sup>11</sup> The preparation of the various metallic formates and acetates is given under their particular systems below.

Every possible precaution was taken to prevent entrance of moisture during determinations or contamination of materials with moisture before use. The extremely hygroscopic nature of certain of the salts restricted work on systems in which they formed one component to dry, cold days.

In some cases the compounds isolated were stable in the region of their melting points, and their compositions were consequently obtained immediately from the curves. When transition to another phase occurred

more interesting curves are also given in the accompanying diagrams. Compositions are expressed in molecular percentages throughout;  $T$  denotes the temperature of initial solidification.

### Results. (A) Formic Acid Systems.

**Potassium formate:Formic acid.**—The potassium salt was prepared by dissolving a pure sample of potassium carbonate in 90% formic acid. After all of the carbon dioxide had been expelled by heating, the hydrated salt was crystallized from the solution. This compound (which is exceedingly hygroscopic) was dried as completely as possible by prolonged heating just below its melting point; the last traces of moisture were removed by recrystallization from absolute ethyl alcohol and desiccation over 99% sulfuric acid *in vacuo*. The final product melted at  $167.5 \pm 0.5^\circ$ , which compares very favorably with the previously recorded value of Groschuff,<sup>12</sup>  $157^\circ$ .

The above results are reproduced graphically in Fig. 1. Three acid salts have been isolated, of which one (the equimolecular compound H.COOK, H.COOH) is stable right up to its melting point,  $108.6^\circ$ . This salt has been previously reported by Groschuff, but his statement that it undergoes transition before melting is obviously unjustified. The two remaining compounds have not been isolated before. Analysis of solid phase (c) gave an acid content of  $67.9 \pm 1.0$  mol. %, evidently corresponding to the compound H.COOK, 2H.COOH. Because of the low temperature ( $-17.5^\circ$ ) at which it undergoes transition, the composition of solid phase (b) could not be definitely determined. From the slope of the curve, however, the probable formula H.COOK, 3H.COOH is deduced.

**Ammonium Formate: Formic Acid.**—The ammonium salt was prepared by passing ammonia into 90% formic acid. Towards the end of the absorption, the temperature was raised sufficiently to ensure the deposition of the neutral (instead of the acid) salt. The product obtained was recrystallized from absolute alcohol and then desiccated over  $\text{P}_2\text{O}_5$ . The melting point of the final material was  $117.3 \pm 0.2^\circ$ .

Fig. 1.—(A) Potassium formate:formic acid (subtract  $30^{\circ}$  from the temperature readings); (B) ammonium formate:formic acid.

Two distinct acidsalts are indicated, as will be seen from the diagram (Fig. 1). Both undergo transition before their melting points are reached, but in the case of solid phase (b) the curve so nearly reaches its maximum point before the salt becomes unstable that it is possible to assign to the compound the formula  $\text{H.COO.NH}_4, 3\text{H.COOH}$  and the approximate melting point of  $-29^{\circ}$ . The remaining compound exists in two different crystalline modifications, the stable form appearing from solution as needles, the unstable as prisms. Analyses of both forms gave the same acid content ( $49.4 \pm 0.6$  mol. % acid), indicating the equimolecular salt<sup>13</sup>  $\text{H.COO.NH}_4, \text{H.COOH}$ .

<sup>13</sup> This compound has been previously isolated in investigation by Reik (*Monats.*, 23, 1033).

**Sodium Formate:Formic Acid.**—The sodium salt was prepared from a reputed c. p. sample by two recrystallizations from water and desiccation at  $140^{\circ}$  to constant weight. The melting point obtained was  $255 \pm 1^{\circ}$ ; the value given by Groschuff is  $253^{\circ}$ .

(a) Solid phase  $\text{H.COONa}$ .

$T$ .....	45.1	63.6	81.2	99.3	118.6	135.2	137.7

Two acid salts are shown by the curves (see Fig. 2), both becoming unstable before their melting points are reached. Analyses of solid phase (b) gave an acid content of  $66.1 \pm 0.5$  mol. %, corresponding to the compound  $\text{H.COONa}$ ,  $2\text{H.COOH}$ . Analyses of solid phase (c) gave an acid content of  $50.1 \pm 0.2$  mol %, corresponding to the compound  $\text{H.COONa}$ ,  $\text{H.COOH}$ .

Fig. 2.—(A) Sodium formate:formic acid; (B) sodium acetate:acetic acid.

The curve could not be extended to the pure neutral salt, owing to the decomposition of the acid at temperatures above  $160^{\circ}$ . This places an automatic upper limit upon all other systems in which formic acid is one component.

It may be noted that the previous results of Groschuff upon this system are entirely in error.

**Lithium Formate:Formic Acid.**—Lithium formate was prepared from a pure sample of the carbonate and 90% formic acid. The hydrated salt which crystallized out from the solution was dehydrated at  $100^{\circ}$ , and final purification secured by recrystallization from alcohol and desiccation over sulfuric acid *in vacuo*.

(a) Solid phase  $\text{H.COOH}$ .

% $\text{H.COOLi}$	0.0	1.58	3.47	5.33	7.09	8.93	10.75	12.23	13.99

% $\text{H.COOLi}$	33.04	35.01	36.13	...	...	....	....	....
T.....	150.4	159.1	163.5	...	...	....	....	....

Contrary to expectations, no acid salts are indicated. The curve could not be carried to completion, but analyses of solid phase (b) showed it to be the neutral salt.

**Barium Formate:Formic Acid.**—The barium salt was obtained by the action of 90 % acid on the carbonate, as described above. It was recrystallized from water 3 times and dried to constant weight at  $140^\circ$ .

(a) Solid phase  $\text{H.COOH}$ .

% $(\text{H.COO})_2\text{Ba}$	0.0	0.91	1.74	2.30	3.73	4.67	5.12	6.95
T.....	8.4	7.2	6.1	5.1	2.6	0.5	-0.3	-4.9

(b) Solid phase  $(\text{H.COO})_2\text{Ba}$ ,  $\text{H.COOH}$ .

% $(\text{H.COO})_2\text{Ba}$	8.52	8.86	9.23	9.83	10.03	10.75
T.....	9.5	15.5	19.0	24.9	26.5	31.8

Owing to extreme retardation in the attainment of equilibrium<sup>14</sup> the system could not be investigated at concentrations greater than 10.7 mol % salt.<sup>15</sup> Analyses of solid phase (b) gave an acid content of  $50.6 \pm 0.7$  mol %, corresponding to the compound  $(\text{H.COO})_2\text{Ba}$ ,  $\text{H.COOH}$ . This salt has not been previously reported.

**Calcium Formate:Formic Acid.**—The method of preparation for calcium formate was the same as given for the barium salt.

(a) Solid phase  $\text{H.COOH}$ .

% $(\text{H.COO})_2\text{Ca}$	0.0	0.16	0.48	0.71	0.93	1.27	1.53
T.....	8.4	8.1	7.7	7.4	7.2	6.9	6.6

(b) Solid phase  $(\text{H.COO})_2\text{Ca}$ .

% $(\text{H.COO})_2\text{Ca}$	0.39	0.57	0.83	1.10	1.26	1.35	1.54	1.61
T.....	128.6	100.0	79.0	61.0	49.7	45.5	35.0	30.0

Analyses showed solid phase (b) to be the neutral salt. As will be seen from the curve (Fig. 3), this exhibits retrograde solubility in formic acid, the solubility at  $130^\circ$  being less than a quarter of that at  $30^\circ$ . It is interesting to find that a phenomenon which is so characteristic of calcium salts in aqueous solutions is here again evident.

**Magnesium Formate:Formic Acid.**—The salt was prepared by dissolving c. p. magnesia in 90 % acid, and dehydrating the product obtained (a dihydrate) to constant weight at  $110^\circ$ . Analysis showed that hydrolysis and consequent loss of acid during dehydration was negligible.

No curve could be obtained for this system owing to the insolubility of the salt in the pure acid. At  $25^\circ$  the saturated solution contains only 0.20 mol % of salt. At-

<sup>14</sup> Compare the system  $\text{BaSO}_4\text{:H}_2\text{SO}_4$ ; Kendall and Davidson, *loc. cit.*

<sup>15</sup> The last points determined represent metastable equilibria, since the solutions deposit, on long standing, crystals of a different form, probably the neutral salt. The solubility curve for this phase must be extremely steep, since a mixture containing 11 mol % of salt did not give a clear solution even at  $140^\circ$ .

tempts to obtain values at higher temperatures failed, equilibrium conditions in the sealed bulbs not being attainable.

**Zinc Formate:Formic Acid.**—The neutral salt was prepared from the carbonate. Its solubility in formic acid is practically zero, a mixture containing less than 0.16 mol % of salt not giving a clear solution even at 140°.

**Nickel Formate:Formic Acid.**—The hydrated salt was prepared from the carbonate and 90% acid, recrystallized from water, and dehydrated at 140°. The neutral salt obtained was soluble in formic acid to an extent of less than 0.10 mol % at 140°.

**Lead Formate:Formic Acid.**—The lead salt was prepared by precipitation from lead nitrate and sodium formate in aqueous solution. The precipitate was thoroughly washed, recrystallized twice from water and dried at 140°.

(a) Solid phase  $(\text{H.COO})_2\text{Pb}$ .

% $(\text{H.COO})_2\text{Pb}$	0.21	0.30	0.42	0.51
T.....	20.0	73.1	109.4	124.5

The solubility, while still extremely slight, is just measurable in this system. While the solid phase in equilibrium with the solutions could not be analyzed, the steepness of the curve leaves little doubt that it is the neutral salt.

**Copper Formate:Formic Acid.**—The hydrated salt was prepared from a pure sample of basic carbonate and 90% acid. After recrystallization from water it was dehydrated to constant weight at 80°, the bright blue neutral salt being obtained.<sup>15</sup> The solubility of this in pure formic acid is less than 0.10 mol % at 140°.

**Silver Formate:Formic Acid.**—Strenuous efforts were made to investigate this system, but the instability of the silver salt rendered all determinations useless. In the presence of water the salt decomposes extremely rapidly. It may be isolated by precipitation in absolute methyl alcohol, but the product so obtained decomposes during desiccation over sulfuric acid even though protected from the light.

Fig. 3.—Calcium formate: formic acid.

## (B) Acetic Acid Systems.

**Sodium Acetate:Acetic Acid.**—The salt was prepared from a c. p. hydrate, which was recrystallized from water and dehydrated to constant weight at 140°. Analysis showed complete removal of water.

(a) Solid phase  $\text{CH}_3\text{COOH}$ .

% $\text{CH}_3\text{COONa}$	0.0	0.83	3.59	5.40
T.....	16.5	16.1	14.3	13.1

<sup>15</sup> Voss, *Ann.*, 266, 33 (1891).

(b) Solid phase  $\text{CH}_3\text{COONa}$ ,  $2\text{CH}_3\text{COOH}$ .

% $\text{CH}_3\text{COONa}$	7.11	8.92	12.17	15.27	16.58	21.55	26.86	30.72	33.03	33.16
T.....	25.3	36.7	54.3	66.9	71.9	85.7	93.2	96.1	96.25	96.3

(c) Solid phase  $\text{CH}_3\text{COONa}$ ,  $\text{CH}_3\text{COOH}$ .

% $\text{CH}_3\text{COONa}$	34.03	36.87	39.06	42.54	44.25	46.28
T.....	112.0	132.3	145.2	157.0	160.6	162.3

(d) Solid phase  $\text{CH}_3\text{COONa}$ .

% $\text{CH}_3\text{COONa}$	48.76	49.49
T.....	174.4	195.5

Two acid salts are indicated by the curves (see Fig. 2); both undergo transition just before reaching their maxima. By slight extrapolations on the diagram, however, the compositions of the compounds are obtained as  $\text{CH}_3\text{COONa}$ ,  $2\text{CH}_3\text{COOH}$  and  $\text{CH}_3\text{COONa}$ ,  $\text{CH}_3\text{COOH}$ , with melting points of  $96.3^\circ$  and  $164^\circ$  respectively. Both of these salts have been previously reported,<sup>17</sup> but the melting points given ( $80^\circ$  and  $140^\circ$ ) are considerably too low.

**Calcium Acetate:Acetic Acid.**—Anhydrous calcium acetate was found to be only slightly soluble in acetic acid. At  $30^\circ$  the saturated solution contains less than 0.35 mol % salt; no attempt was made to follow the curve to higher temperatures.

**Zinc Acetate:Acetic Acid.**—A c. p. sample of the salt was dehydrated at  $100^\circ$ . The anhydrous salt is practically insoluble in the pure acid, a mixture containing 0.10 mol % of salt giving a clear solution only at  $130^\circ$ .

**Ferric Acetate:Acetic Acid.**—A solution of ferric acetate in 90% acetic acid was treated with acetic anhydride and the mixture refluxed. The crystals deposited on cooling were dried with ether. Analysis showed the product obtained to be anhydrous and very slightly basic. The solubility in acetic acid was practically zero, a mixture containing only 0.07 mol % of salt not giving a clear solution even at  $140^\circ$ .

**Silver Acetate:Acetic Acid.**—The silver salt was prepared by precipitation from silver nitrate and sodium acetate. The precipitate was washed thoroughly, recrystallized from water and dried to constant weight over sulfuric acid *in vacuo*.

(a) Solid phase  $\text{CH}_3\text{COOAg}$ .

% $\text{CH}_3\text{COOAg}$	0.094	0.204
T.....	76.	115.

As will be seen, the solubility in acetic acid is very small. The measurements could not be carried to higher temperatures, owing to decomposition of the salt.

### Consideration of Results.

**Compounds isolated and their stability.**—The only formates that have been found to give isolable acid salts with formic acid are those of potassium, ammonium, sodium and barium. Of the 8 compounds obtained (one of which is existent in two crystalline modifications), only one is of sufficient stability to reach its melting point before undergoing transition. This is the equimolecular acid potassium salt, melting at  $108.6^\circ$ .

Obviously compound formation is here, as in the corresponding case of sulfates, most pronounced with the more electropositive metals, falling off rapidly as the electrode potential of the metal approaches that of hydrogen.

<sup>17</sup> Lescoeur, *Ann. chim. phys.*, [6] 28, 241 (1893). Vasiliev (*J. Russ. Phys. Chem. Soc.*, 41, 753 (1909)) has also studied the cryohydric point of this system.

The acid formates of potassium are more stable than those of sodium,<sup>18</sup> barium formate gives a single acid salt, while calcium and magnesium formates show no isolable compounds. Owing to the instability of silver formate, the increase in compound formation for metals below hydrogen in the electromotive series, so well illustrated in the case of the sulfates, is not here observable.

With acetates in acetic acid, although the full series has not been examined, the same behavior is evident. Sodium acetate gives 2 acid salts, both of which decompose just before reaching their melting points. Compounds of potassium,<sup>19</sup> ammonium<sup>20</sup> and lithium<sup>21</sup> acetates with acetic acid have been reported by previous investigators. The acetates of the less electropositive metals are practically insoluble in acetic acid.

It is of importance to note that the rate at which compound formation decreases in stability, as we go down the series from potassium to hydrogen, increases as the acid radical becomes weaker. Thus isolable acid sulfates are obtained even with zinc and ferrous iron, but the last isolable acid formate is reached as high up as barium. In general, therefore, the stability of the acid salts of any particular metal increases with the strength of the acid radical. Thus silver sulfate gives two acid salts with sulfuric acid, while silver acetate in acetic acid is scarcely soluble. Sufficient scattered observations may be collected from the literature to test this generalization for two other acid radicals. Acid *fluorides* have been reported for lithium,<sup>22</sup> potassium,<sup>23</sup> sodium,<sup>24</sup> ammonium<sup>25</sup> and silver.<sup>26</sup> With the last-named metal, 2 compounds (AgF, 3HF and AgF, HF) have been isolated; evidently compound formation in this series approaches in stability that given by the sulfates. With the much weaker *hydroxyl* radical, on the other hand, no tendency towards the formation of complexes is exhibited except with the highly electropositive metals. The only hydroxides which give isolable hydrates are those of the alkali metals,<sup>27</sup> ammonium,<sup>28</sup> barium<sup>29</sup> and strontium.<sup>30</sup>

<sup>18</sup> Lithium, the most electropositive metal of all, is out of line in giving a negative result; this, however, is a point which will be taken up later.

<sup>19</sup> Lescoeur, *Ann. chim. phys.*, [6] 28, 245 (1893); Melsens, *Compt. rend.*, 19, 611 (1844).

<sup>20</sup> Reik, *Monats.* 23, 1033 (1902).

<sup>21</sup> Lescoeur, *Bull. soc. chim.*, 24, 517 (1875).

<sup>23</sup> Moissan, *Compt. rend.*, 106, 547 (1888).

<sup>24</sup> Abegg, *op. cit.*, p. 220.

<sup>25</sup> Marignac, *Ann. min.*, [5] 15, 221 (1859).

<sup>26</sup> Gore, *Proc. Roy. Soc.*, 18, 157 (1870); Guntz, *Bull. soc. chim.*, [3] 13, 114 (1895).

<sup>27</sup> Pickering, *J. Chem. Soc.*, 63, 890 (1893).

<sup>28</sup> Rupert, *THIS JOURNAL*, 31, 866 (1909); 32, 148 (1910).

<sup>29</sup> Abegg, *op. cit.*, [2] 2, 259 (1905).

<sup>30</sup> Müller-Erzbach, *Ber.*, 20, 1628 (1887); 22, 3180 (1889).

**Solubility Relationships.**—The parallelism between compound formation and solubility discovered in the case of the sulfates is again obvious in this work. The alkali formates are exceedingly soluble in formic acid, the salts of less electropositive metals are decreasingly soluble, practically zero solubility is shown by the formates of metals below magnesium in the electromotive series. The following table<sup>31</sup> exhibits the quantitative results at a single fixed temperature (25°).

Metal.	Electrode potential.	Mol % solubility 25°.	Solid phase.
Li	—3.02	23.7	H.COOLi
K	—2.92	25.5	H.COOK, H.COOH
Ba	—2.8 (?)	9.8	(H.COO) <sub>2</sub> Ba, H.COOH
Na	—2.72	21.3	H.COONa, 2H.COOH
Ca	—2.5 (?)	1.7	(H.COO) <sub>2</sub> Ca
Mg	—1.55	0.2	(H.COO) <sub>2</sub> Mg
Zn	—0.76	<0.1	(H.COO) <sub>2</sub> Zn
Ni	—0.22	<0.1	(H.COO) <sub>2</sub> Ni
Pb	—0.13	0.2	(H.COO) <sub>2</sub> Pb
Cu	+0.35	<0.1	(H.COO) <sub>2</sub> Cu

In the acetic acid series, solubilities follow the same course, as far as can be judged from the limited results available. Sodium acetate is very soluble in acetic acid, calcium acetate only slightly soluble, the acetates of less electropositive metals practically insoluble.

### Summary.

An examination of the freezing-point curves of metal formates in formic acid has resulted in the isolation of the following compounds.

Salt.	Acid compounds isolated.
Potassium formate	(a) H.COOK, 3H.COOH } (not previously reported)
	(b) H.COOK, 2H.COOH }
	(c) H.COOK, H.COOH; m. p. 108.6°
Ammonium formate	(a) H.COONH <sub>4</sub> , 3H.COOH (not previously reported)
	(b) H.COONH <sub>4</sub> , H.COOH; existent in 2 crystalline modifications
Sodium formate	(a) H.COONa, 2H.COOH (not previously reported)
	(b) H.COONa, H.COOH
Barium formate	(H.COO) <sub>2</sub> Ba, H.COOH (not previously reported)

The neutral formates of lithium, calcium, magnesium, zinc, nickel, lead and copper gave no isolable acid salts.

A few corresponding curves for metal acetates in acetic acid have been determined. With sodium acetate 2 acid salts (CH<sub>3</sub>.COONa, 2CH<sub>3</sub>.COOH

<sup>31</sup> Compare Kendall and Davidson, *loc. cit.*, p. 989. The only marked irregularity in the present table consists in the superior solubility of sodium formate over that of barium. This will be discussed in connection with the "valence factor" in compound formation in a later paper.

and  $\text{CH}_3\text{COONa}$ ,  $\text{CH}_3\text{COOH}$ ) were isolated; calcium, zinc, ferric and silver acetates gave negative results.

The results of this work resemble those obtained with sulfate systems in following the general rule previously deduced, that compound formation increases in extent with increasing diversity in the character of the components, the significant variable in systems of this general type  $\text{HX}:\text{RX}$  being the position of R relative to H in the electromotive series. An examination of the data for sulfates, formates, acetates, fluorides and hydroxides shows that the rate of decrease in compound formation as we proceed from more positive radicals (such as potassium) or less positive radicals (such as silver) towards hydrogen increases, the weaker the acid radical.

Solubility and compound formation are again found to proceed in parallel throughout the series. Salts which show extensive compound formation (such as salts of the alkali metals) are also extremely soluble. As we pass down the electromotive series towards hydrogen, solubility rapidly diminishes and finally becomes inappreciable.

The correlation of solubility with compound formation and of compound formation with ionization in solutions of metal formates in formic acid will be further dealt with in subsequent communications, and additional rules connecting these properties in systems of the general type  $\text{HX}:\text{RX}$  will there be formulated.

## THE PREDICTION OF SOLUBILITY IN POLAR SOLUTIONS.

BY JAMES KENDALL, ARTHUR W. DAVIDSON AND HOWARD ADLER.

Received March 3, 1921.

If all solutions were ideal, the answer to most of our solubility problems could be very simply stated.<sup>1</sup> At any given temperature the solubility of a solid substance A in a series of different solvents B, C, D, etc. would be, when expressed in terms of mol fractions, a fixed quantity, independent of the particular solvent and immediately calculable from the heat of fusion of A, the temperature of fusion of A and the specific heats of A in the solid and liquid states. All liquids would be completely miscible under all conditions. The solubility of a gas in a liquid, expressed again in terms of mol fractions, would depend only upon the ratio of its partial pressure over the solution to its vapor pressure in the liquid state at the same temperature.<sup>2</sup>

<sup>1</sup> Roozeboom, "Heterogene Gleichgewichte," [1] 2, 273, et seq. (1904); Washburn, "Principles of Physical Chemistry," Chap. 14 (1915).

<sup>2</sup> Strictly speaking, this would be true only for a perfect gas. More accurately, solubility is proportional to fugacity instead of to vapor pressure.

Unfortunately, we meet ideal solutions in the laboratory scarcely more frequently than we do infinitely dilute solutions, so that the theory of ideal solutions alone is not much more useful to us in the quantitative prediction of solubilities than is the simple theory of van't Hoff in the quantitative prediction of osmotic pressures or allied relationships. Certainly, for example, the solubility of iodine<sup>3</sup> is not the same in a series of solvents such as water, ethyl alcohol, chloroform, carbon disulfide and bromine at the ordinary temperature, even if translated from the units usually employed into terms of mol fractions.

In order to make any further advances on the basis of our modern theory of ideal solutions we require, therefore, to investigate very carefully the various factors which induce non-ideality in solutions and the effect each of these factors has on solubility phenomena. Apparently so many different points<sup>4</sup> are involved that the complexity of the problem, when first realized, almost compels us to despair of ever reaching definite conclusions; yet on critical examination it becomes possible to disentangle to some extent fundamental from secondary factors, and, by concentrating attention exclusively upon the former, to obtain at least a preliminary outline of the more comprehensive theory of solutions of the future.

This narrowing down of the point of attack may, of course, be carried too far, but in such a case vital disagreements between predicted and experimental results soon appear, necessitating a re-examination of the field already covered and leading either to the modification or to the amplification of the generalizations involved. Thus the tendency of most investigators in the field of non-ideal solutions has been to attribute all divergences from the ideal-solution equations to effects which may be called purely chemical, *i. e.*, to changes in the molecular state of the components on admixture.<sup>5</sup> In a recent extremely valuable series of articles by Hildebrand and his associates, however, the primary importance of taking into consideration two entirely distinct factors of a more physical nature, internal pressure and polarity, has been indisputably established.<sup>6</sup> The conclusions of Hildebrand with respect to the solubilities of solids in liquids (that section of the field to which the present article is restricted) may be

Electromagnetic environment as a factor in solubility has also been considered by Harkins (*ibid.*, 41, 970 (1919)).

summarized as follows: (1) the solubility of a non-polar substance in a non-polar liquid of equal internal pressure is that calculated on the basis of the ideal-solution theory; (2) where the internal pressures are unequal, the solubility is less, to an extent depending on the difference in internal pressures; (3) when one substance is polar and the other non-polar, the solubility is also less; (4) when both substances are polar (leading frequently to the formation of recognizable compounds) the solubility is usually greater than the calculated value.

Numerous examples are given by Hildebrand to illustrate the first three of these rules. The greater difficulties inherent in the study of solutions of the fourth type (polar substances in each other) have also been briefly indicated.<sup>7</sup>

It is with this fourth class of solutions, particularly with those cases in which the formation of addition compounds between the components has already been extensively studied, that the present investigation is concerned. In previous articles<sup>8</sup> general rules have been formulated connecting the extent of compound formation with the difference in character<sup>9</sup> of the components of the solution, and for two series of systems of the type  $HX - RX$  a parallelism between compound formation and solubility throughout each series has been traced.<sup>10</sup> The fundamental significance of this parallelism is here discussed and its extension to other series attempted.

Before proceeding to a theoretical examination of these solutions (which belong, as indicated above, to the most complex of the 4 divisions made by Hildebrand) it is necessary to determine how many of the disturbing factors may legitimately be neglected, since only through such a clearing of the field in advance is it possible at the present stage to simplify matters sufficiently to enable us to formulate and put to the test any generalizations whatever.

In the first place, for the particular cases here examined, the factor of internal pressure may—in spite of what has been said above—be temporarily left out of consideration. Hildebrand<sup>11</sup> himself admits that there is more justification in restricting the discussion to purely chemical factors in mixtures involving a polar liquid; and the components of the mixtures

<sup>9</sup> *I. e.*, differences in the positive or negative nature of the constituent groups. In the case of systems of the simple type  $HX - RX$  here studied, where the negative radical  $X$  is common to both components, the difference in character is dependent on the relative positions of  $R$  and  $H$  in the electromotive series.

<sup>11</sup> Hildebrand, *THIS JOURNAL*, 38, 1461 (1916); see also Eastman and Hildebrand *ibid.*, 36, 2029 (1914).

investigated in this article are *both* polar. In a later section,<sup>12</sup> indeed, it will be shown that it is extremely improbable that the main conclusions here drawn can be significantly affected through not taking into account the differences in internal pressure of our components. The polarity factor, owing to its inherent complexity, cannot be disposed of so readily, but by dissecting the general term "polar," as applied to a liquid, into its particular consequences<sup>13</sup>—increased internal pressure, abnormalities in surface tension and other physico-chemical relationships, increased molecular complexity both in the pure state (association) and in solution with other polar substances (addition compound formation), and an increased tendency towards ionization—we can examine the effect of each of these in turn and so establish its relative importance in inducing deviations from ideality in the special class of solutions under study.

The results obtained in earlier papers of this series<sup>14</sup> lead us to conclude that *compound formation* between the components is the dominating point to be considered. *Internal pressures* in any particular system may vary considerably with the composition, but it has already been indicated that this factor can be here omitted. The abnormalities in other physical properties do not need to be taken into account in this work. *Ionization* has been shown to be a consequence of compound formation, and to parallel it in extent throughout any given series. Any divergences from the ideal solution laws due to compound formation between the components will, therefore, be accentuated by the accompanying ionization, it is true. But it is not to be expected that ionization will change the order of deviations from the ideal curve predicted for a series of systems on the basis of compound formation alone. Rather it will make the "spread" of the different curves with respect both to the ideal and to each other still more pronounced. A detailed discussion of the last remaining factor—*association* of the components—unfortunately cannot be entered into at this point for space considerations. In the final consideration of results,<sup>15</sup> however, it will be shown that the effect of this factor also is here, in general, only of secondary consequence.

We are now in a position to attack the problem in a simpler form, by investigating first of all the influence of compound formation alone upon ideal solution and solubility relationships. Rules for this factor having once been established, we can later proceed more readily to the consideration of the remaining factors.

<sup>15</sup> A preliminary treatment of this complicated subject is given by Roozeboom, "Heterogene Gleichgewichte," [1] 2, 303-14 (1904).

### The Effect of Compound Formation on the Ideal Solubility Curve.

The first stage of the problem consists in indicating qualitatively how the solubility of a fixed substance A will vary in a series of different solvents exhibiting gradually increasing compound formation with A in the liquid state. The complete solubility curves for such a series of systems are shown on a single diagram in Fig. 1. In this diagram, temperature is plotted against the molecular composition of the saturated solution. To facilitate comparison of the curves it is necessary to note that the point A represents the same temperature throughout—the melting point of pure substance A.

point of pure A, and  $R$  the gas constant 1.9852. The form and slope of this curve are conditioned solely by the ratio  $Q/T_0$ . If this ratio exceeds the value 4 (as it does for all substances except a few elements) the curve is concave throughout its whole course with respect to the composition axis, but does not change in slope greatly until  $x$  becomes very small, when it commences to dip sharply,  $x$  finally becoming zero at absolute zero of temperature. The solubility curve of  $B_I$  in A, the line  $B_ID$ , is similar in character (its slope depending, however, on the values of  $Q$  and  $T_0$  for  $B_I$ ). The stable portions of the two curves end at their point of intersection, E, the eutectic point of the system.

Curves II to V illustrate the successive changes which occur in the diagram as compound formation increases.<sup>18</sup> In Curve II the compound formed is so highly dissociated in solution that its solubility curve FGH never enters the stable region of the diagram; in Curve III compound formation is somewhat more extensive and the solubility curve of the compound  $AB_{III}$  possesses a limited stable interval KL; in Curve IV this interval has expanded sufficiently to exhibit a maximum point at G (in other words, the compound  $AB_{IV}$  is stable at its melting point); in Curve V, finally, the compound  $AB_V$  is not dissociated at all into its components in the solution, the system consisting, indeed, of two simple systems of the type shown in Curve I compressed into one composition range.

The essential point to be noted in these systems is the depression of the curve AC from its ideal position, which compound formation in solution necessitates.<sup>19</sup> If only part of the total A in solution exists as uncombined A then, since the solution will not become saturated with respect to A until the mol fraction of *uncombined* A reaches the ideal value, the mol fraction of A in the saturated solution must exceed

that we are approaching somewhat too closely systems of the type studied by Hildebrand (where internal pressure differences cannot be kept out of consideration), yet a uniform increase in solubility throughout each series is apparent.

### Solubilities of Different Substances in a Fixed Solvent.

This second stage of the problem (the comparison of the solubilities of a series of different solutes in the same solvent) is in practice the more important, owing to the supremacy of water as a solvent liquid. Theoretically, however, it is still more difficult to handle, for while the ideal solubility curve for each particular solute is fixed by its own values for  $Q$  and  $T_0$ , no relation between the values of either  $Q$  or  $T_0$  for *different* solutes has yet been established. We cannot therefore postulate in advance the relative positions of a series of ideal curves, much less make comparisons between them when compound formation causes deviations from the ideal. Under special circumstances, however, it is still possible to make some progress, namely when the solutes possess melting points far above the temperature at which we wish to conduct comparisons. The most interesting of all classes of solutes—neutral salts—fortunately falls under this category. For the discussion of solubility relationships in this field, reference should be made to Fig. 2.

in other words, the solubility is *practically zero*. If we take, as an example, the case of potassium chloride (for which  $Q$  is 64.10 cal. and  $T_0$  is  $1045^\circ$  abs.) we find that the mol fraction of the salt in a saturated ideal solution at  $25^\circ$  would be only 0.00044.<sup>23</sup>

If the salt forms a compound AB with the solvent, however, the solubility curve is depressed (as in Fig. 1) to an extent dependent upon the stability of the compound in solution, the successive changes which occur being shown in Curves II to V, as before.<sup>24</sup> The curve  $A_V C_V$ , which represents saturated solutions of a solute  $A_V$  forming a perfectly stable compound of the type AB, is tangential to the AB composition axis ( $x = 0.5$ ); the remaining curves again assume intermediate positions. Furthermore, since the curves are all falling exceedingly sharply in the lower portion of their courses, the variation of  $x$  with  $T$  at low temperatures is very small. It becomes a matter of minor importance, therefore, what the actual values of  $Q$  and  $T_0$  for each particular solute may be, since although the curves for the various salts intersect at random at high temperatures, at low temperatures the order of solubility will be substantially identical with the order of compound formation. As in Fig. 1 this may best be seen by comparing the positions of the points  $X_I$ ,  $X_{II}$ ,  $X_{III}$ ,  $X_{IV}$  and  $X_V$  on the various curves at a fixed temperature  $T$ . For strict purposes of comparison, it must be noted, it is essential that this temperature be so chosen that the solubility of the simple salt is determinable in each case. At still lower temperatures, where a compound may make its appearance as stable phase and the solubility of the simple salt may no longer be measurable, the solubility order may become obscured by the intersection of the stable curves, as indicated by the positions of the points  $X'_I$ ,  $X'_{II}$ ,  $X'_{III}$  and  $X'_V$  at the temperature  $T$ .<sup>1</sup> It must be emphasized that the solubility of the compound under such conditions affords no accurate guide to the actual solubility of the simple salt, but is useful in indicating its *minimum* value.<sup>25</sup>

For a series of different salts of high melting points in a fixed solvent at a sufficiently low temperature, therefore, solubility and compound formation again proceed in parallel. Two typical series which illustrate this rule (neutral sulfates in sulfuric acid and neutral formates in formic acid) have already been presented in previous articles, to which reference should be made for the complete tables. A third precisely similar series (metal hydroxides in water) may here be added for comparison.

<sup>23</sup> For a saturated aqueous solution, this is equivalent to about 1.8 g. per liter (approximately 0.02  $N$ ).

<sup>24</sup> Curve IV is omitted in order to avoid crowding and confusion in the diagram. Its position, however, between Curves III and V can readily be visualized with the aid of Fig. 1.

<sup>25</sup> The solubility of an unstable solid phase is necessarily greater than that of the stable solid phase.

The metals are arranged in the order of their electrode potentials. As in the two earlier series, it will be evident that the relative position of each metal to hydrogen in the series is the determining factor in compound formation, ionization and order of solubility. The hydroxides of those metals in the immediate neighborhood of hydrogen form no isolable hydrates, are practically non-ionized in solution and insoluble. As we proceed away from hydrogen towards the more electropositive metals we find isolable hydrates appearing and solubility increasing. The series culminates in the alkali hydroxides, which give a large number of very stable hydrates, are very highly ionized and are exceedingly soluble in water. The irregularities among the alkali metals themselves are to be ascribed to the fact that the solubilities of their non-hydrated hydroxides cannot be directly measured, the figures given being merely minimum values, as explained above.

As in the case of the formates, the available data for confirming an increase in hydration, ionization and solubility for metals below hydrogen are not very plentiful. Silver hydroxide is not stable in the solid state, so

that its solubility cannot be directly measured. It does exist in solution, however, as a moderately strong base,<sup>26</sup> and the solubility of this in water must be in excess of that of the more stable silver oxide.

The only marked exception, as before, is offered by aluminum; in spite of the high electrode potential of the metal, aluminum hydroxide is highly insoluble and is an exceedingly weak base. This abnormality<sup>27</sup> will be discussed later.

### Systems of the Type RX:HOH.

It is not possible to extend the general rules deduced for systems of the type RX:HX to other series of salts in water (where the system contains no radical common to both components) very far at present. The rules outlined above may be tentatively applied, however, to systems of the type RX:HOH for those particular series in which either R is not very different in character from H, or X is not very different in character from OH. In other words, we find that salts of a very weak base exhibit, in general, increasing hydrate formation and increasing solubility in water as the acid radical X diverges from OH, while salts of a very weak acid show the same behavior as the metal radical R diverges from H. Two illustrative series are presented below.

Approximate value only.<sup>f</sup> Bineau, *Compt. rend.*, 41, 510 (1855). Approximate value only.<sup>g</sup> De Forcrand, *ibid.*, 152, 1210 (1911).<sup>h</sup> Kohlrausch, *Z. physik. Chem.*, 64, 145 (1900).<sup>i</sup> Mylius and Funk, *Ber.*, 30, 1718 (1897).<sup>j</sup> Guntz and Guntz, *Ann. chim.*, 2, 101 (1914). The solubility of the tetrahydrate is changing very rapidly with temperature at 18°, owing to the proximity of the maximum point.<sup>k</sup> Levi, *Gazz. chim. ital.*, [2] 31, 1 (1901).<sup>27</sup> See Kendall and Davidson, *THIS JOURNAL*, 43, 988 (1921); also Heyrovsky, *J. Chem. Soc.*, 117, 1024 (1920).

The results given above for ferrous salts are paralleled by the salts of other exceedingly weak bases (*e. g.*,  $\text{Zn}(\text{OH})_2$ ;  $\text{Cu}(\text{OH})_2$ ), the halides of these metals being all very soluble, the sulfates somewhat less so, and the carbonates, sulfides, etc. all practically insoluble. The strength of the base cannot be increased very far above that of water, however, before these rules become inapplicable. Thus, for example, lead sulfate is insoluble in water while lead acetate is very soluble.

The fluorides in Table VII form a very striking series. Solubility and compound formation both fall off rapidly as we go down the list from potassium to the less positive metals,<sup>28</sup> but with the silver salt the effect of the diversity factor again becomes very apparent. Similar solubility relationships hold, in general, for the salts of other weak acids, such as the carbonates, sulfides and cyanides.<sup>29</sup> In all these series, the salts of the alkali metals are very soluble in water, those of the alkali earth metals less soluble and those of the remaining metals practically insoluble. The rule noted in an earlier article<sup>30</sup> for systems of the type  $\text{HX}:\text{RX}$  when X is varied also applies here, namely that the decrease in solubility as we proceed towards hydrogen in the series is more rapid the weaker the acid radical X. The strength of this radical cannot be increased very far above that of water, however, before we find that all generalizations must be applied with considerable caution. It is somewhat surprising that they should still hold so well in the case of the fluorides.

For salts of a strong acid with a strong base, where we have simultaneously a positive radical very different in character from hydrogen and a negative radical very different in character from hydroxyl, no rules of a general nature can be deduced at present. It is true that Bodländer,<sup>31</sup> more than twenty years ago, made some extremely significant preliminary advances in this field by showing that the solubility of a difficultly soluble salt in water could be approximately calculated from the electrode potentials of its ions and the heat of formation of the solid salt, but the subsequent development of Bodländer's work has by no means equalled its early

<sup>28</sup> The order of barium and sodium is reversed, as in the case of the fluorides in hydrofluoric acid (Kendall and Adler, *loc. cit.*, p. 1479); this point however will be taken up later.

<sup>29</sup> Seidell, *op. cit.* It must be noted that the majority of the values given in the literature for these salts do not represent exact equilibrium data. For example, in the case of the carbonates, a definite solubility is obtained only when the partial pressure of  $\text{CO}_2$  above the solution is fixed (Johnston, *THIS JOURNAL*, 37, 2001 (1915)). Similarly a fixed  $\text{H}_2\text{S}$  pressure is necessary in the case of the sulfides, a point hitherto overlooked in the calculation of their solubilities. The current values (*e. g.*, those given by Weigel, *Z. physik. Chem.*, 58, 293 (1907)) may consequently not be legitimately comparable.

<sup>30</sup> Kendall and Adler, *loc. cit.*, p. 1479.

<sup>31</sup> Bodländer, *Z. physik. Chem.*, 27, 55 (1898).

promise,<sup>32</sup> and criticisms have been abundant.<sup>33</sup> Certain of these criticisms (such as the fact that the heat of formation of a compound is not an exact measure of the free energy change) were forestalled by Bodländer himself, but the really fundamental weakness in his method—the total neglect of the part played by the *solvent* in solubility phenomena—has not previously been sufficiently emphasized. It is due to this neglect that the rules formulated by Bodländer<sup>34</sup> regarding the relative solubilities of series of salts containing the same acidic or basic radical (rules which are substantially similar, for certain series, to those developed above) are restricted to aqueous solutions, and even there display disconcerting discrepancies.<sup>35</sup> Certainly the equilibria involved in aqueous salt solutions, owing to interaction between solvent and solute, are much more complicated than Bodländer assumed.<sup>36</sup> We can, however, by taking into consideration the effect of the formation of solvent-solute complexes on solubility relationships, not only carry the qualitative study of the question for the particular case of aqueous solutions to a point beyond that reached by Bodländer, but we can also apply the rules obtained to the more general field of non-aqueous solutions. A very brief survey of a few typical series is all that can be presented at this stage.

### The Solubility of Salts in Non-aqueous Solvents.

It has been claimed by Walden that the solubility of a salt in a series of solvents is greater the greater the degree of association (*i. e.*, the more marked the polar nature) of the solvent.<sup>37</sup> In the so-called "indifferent" solvents (such as hexane, benzene, ether) where compound formation is practically non-existent and where, furthermore, the difference in internal

<sup>32</sup> Abegg and Bodländer, *Z. anorg. Chem.*, **20**, 457 (1900); **34**, 180 (1903); *Am. Chem. J.*, **28**, 220 (1902).

<sup>33</sup> Ostwald, *Z. physik. Chem.*, **32**, 182 (1900); Locke, *Am. Chem. J.*, **27**, 105 (1902); **28**, 403 (1902); Noyes, *Z. physik. Chem.*, **42**, 507 (1903); Hildebrand, *THIS JOURNAL*, **38**, 1452 (1916). The following comment of Roozeboom upon the work of Bodländer is of particular interest: "To me it seems especially suspicious that temperature of fusion and heat of fusion have been left entirely out of consideration, since in ideal solutions these are the factors which absolutely control the solubility curve" (*Heterogene Gleichgewichte*, [1] **2**, 316 (1904)).

<sup>34</sup> Bodländer, *loc. cit.*, p. 69.

<sup>35</sup> Especially among *soluble* salts, where it was found necessary to add to the original theory a "law of self-preservation" to account for inverse solubility results (Abegg and Bodländer, *Am. Chem. J.*, **28**, 222 (1902)).

<sup>36</sup> Compare Kendall, *Proc. Nat. Acad. Sci.*, **7**, 56 (1921); Kendall and Gross, *THIS JOURNAL*, **43**, 1425 (1921).

<sup>37</sup> Walden, *Z. physik. Chem.*, **55**, 703 (1906); **61**, 633 (1908). The rate of increase varies with the degree of association of the salt (see Turner, *J. Chem. Soc.*, **99**, 902 (1911)). An attempt to put Walden's rule upon a mathematical basis has been made by van Laar, *Z. physik. Chem.*, **58**, 567 (1907); **59**, 212 (1907).

pressure is extreme, salts are in general insoluble.<sup>38</sup> As the polarity of the solvent molecule increases, however, compound formation becomes more and more extensive and solubility increases. Where the compounds are sufficiently stable to be isolated from solution (as, for example, the acetic acid or alcohol addition products of calcium chloride) the solubility of the salt is very high.<sup>39</sup>

Walden's rule is only a partial statement of the facts, however. For a salt to be soluble it is not sufficient for the solvent molecule to be polar, its radicals must also be diverse in character from those of the solute. This has already been shown in detail for the 3 series of metal sulfates in sulfuric acid, metal formates in formic acid and metal hydroxides in water. Any salt  $RX$  in its own acid  $HX$ , indeed, necessarily possesses the characteristics of a base,<sup>40</sup> and the diversity of the radicals  $R$  and  $H$  will control compound formation and solubility. This rule may be further illustrated from the work of Franklin on liquid ammonia solutions.<sup>41</sup> Here the typical bases are the metal amides, imides and nitrides. Among those that are known only those of the alkali metals (*e. g.*, potassium amide, where the diversity between  $K$  and  $H$  is extreme) are soluble in ammonia. The ammonobases of the metals nearer to hydrogen (like the corresponding aquo-bases) are not soluble to any extent, and may be conveniently prepared by precipitation.

Aquo-acids and ammono-acids are similarly comparable. Although the majority of the common acids have melting points too low to enable us to discuss systems of the type  $HX:HOH$  in the same definite manner as systems of the type  $ROH:HOH$  in Table V, yet an analogous solubility rule, that strong acids, as a class, are much more soluble than weak acids, is obviously in general accordance with the experimental facts. In liquid ammonia the ammonium salts behave as acids, and here also we find that compound formation and solubility increase with the increasing strength of the acidic radical. Thus ammonium fluoride is insoluble, while the remaining ammonium halides are highly soluble and give very stable addition compounds.<sup>42</sup>

When we attempt to consider salts of other metals in liquid ammonia,<sup>43</sup> we encounter the same difficulties as for salts in aqueous solution. An interesting point<sup>44</sup> to notice, however, is that while hydrate formation and solubility in water are most extensive, in general, with salts of the most

<sup>38</sup> An interesting exception, silver perchlorate in benzene, has recently been critically investigated by Hill, *THIS JOURNAL*, 43, 254 (1921).

<sup>39</sup> Menshutkin, *Mem. Polyt. Inst. Petrograd*, 5, 355 (1906).

electro-positive metals (*e. g.*, Li, K), the tendency to combine with and dissolve in ammonia is most marked for the salts of metals at the other extreme of the electrode potential series (*e. g.*, Hg, Ag). A possible explanation of this dissimilarity is the highly electropositive character of the ammonium group.<sup>45</sup>

Systematic solubility determinations for salts in other liquids are now in progress.

### The Solubilities of Salts in Aqueous Solutions of Other Salts.

So far, only two-component systems have been discussed. We can also gain information, however, regarding the general applicability of the rules here derived for systems of the type  $HX:RX$  to systems of the somewhat more general type  $RX:R'X$  (or  $RX:RY$ ) by examining the effect of the addition of a salt with a common ion upon the solubility of a difficultly soluble salt in water. As a typical illustration, the influence of other chlorides upon the solubility of silver chloride in water may be considered.

Normally, the solubility of silver chloride in water should be depressed practically to zero by the presence of another chloride in quantity, according to the principle of the constancy of the solubility product. If, however, any addition compounds between silver chloride and the added chloride  $MCl$  are formed in solution, then the solubility of silver chloride should exceed the calculated value by an amount dependent upon the stability of the compounds formed. The stability of the addition compounds, furthermore, should depend (according to the generalizations developed above) upon the diversity in the positions of the radicals Ag and M in the electrode potential series. Consequently we should expect the solubility of silver chloride in water to increase more and more above the normal value as the radical M is made more electropositive.

That this is so in actual fact is strikingly shown in Fig. 3, which reproduces the accurate determinations of Forbes.<sup>46</sup> It will be seen that the solubility is tremendously increased in every case shown, the order being  $H < Ca < Na < Sr < Ba < K$  or  $NH_4$ . This is exactly the order in the electrode potential series,<sup>47</sup> as may be seen by reference to Table V. In concentrated

<sup>45</sup> Although it has been shown by Frenzel (*Z. Elektrochem.*, 6, 486 (1900)) that the primary dissociation of ammonia is into  $H^+$  and  $NH_4^+$ , solvation of the positive ion to  $NH_4^+$  must also be admitted (compare Abegg, "Handbuch anorg. Chem.," [3] 3, 58 (1907)).

<sup>46</sup> Forbes, *THIS JOURNAL*, 33, 1937 (1911). The curves run very close together at low concentrations of added salt, consequently to avoid confusing the diagram the data for high concentrations only (above 2*N*) are there included. The solubility of  $AgCl$  in pure water at 25° is 0.0000120 g. equiv. per liter (Glowczynski, *Kolloidchem. Beihefte*, 6, 147 (1914)); practically zero on the scale in the diagram.

<sup>47</sup> The position of  $NH_4$  in the series, which cannot of course be directly determined, has been discussed thoroughly by Abegg ("Handbuch anorg. Chem.," [3] 3, 241-2

aqueous solutions of mercuric chloride, moreover, silver chloride is practically insoluble, as might also have been predicted from the proximity of Ag and Hg (ic) in the same table. For the influence of other chlorides upon the solubility of silver chloride in water no trustworthy data are at present available,<sup>48</sup> but experiments to complete the series are now being carried out in this laboratory.

Fig. 3.

A very wide and promising field for future investigation here offers itself, since it will be obvious that any general conclusions deduced will be of importance not only in themselves but also in the further development of the theory and practice of quantitative analysis. From the results for silver chloride discussed above, for example, it appears that the completeness of the precipitation of this salt from aqueous solution is vitally dependent upon the nature and concentration of other chlorides present.

(1907)); experimental analogies place the radical very close to potassium. In preceding solubility comparisons (Kendall and Davidson, *loc. cit.*, p. 989; Kendall and Adler, *loc. cit.*, p. 1480) the ammonium salts have not been included in view of the fact that their melting points are much lower than those of other salts, but here this factor does not come into consideration.

<sup>48</sup> A few isolated and contradictory determinations are given in Seidell, *op. cit.*, p. 609. A single measurement by Forbes indicating that AgCl is only slightly soluble in concentrated ZnCl<sub>2</sub> solutions, which furnishes the sole incongruity in his whole work with the predictions of the present theory, is being further investigated.

Forbes<sup>49</sup> has calculated that the salt is most insoluble in 0.01 *N* chloride solutions; Glowczynski,<sup>50</sup> on the other hand, has found experimentally that the addition of potassium chloride and ammonium chloride in much lower concentrations already involves an appreciable increase above the original solubility value. Evidently the presence of salts of the alkali metals in considerable quantity could easily introduce very significant errors in the analytical procedure at present employed.<sup>51</sup> The magnitude of such errors might, according to the results here obtained, be reduced by the addition of salts of less electropositive metals, but this is a point which requires direct experimental confirmation.<sup>52</sup> Whether the rules outlined in this article could legitimately be expanded to predict the optimum conditions for precipitations in general is a question for future investigation. The available data for other difficultly soluble salts are in few instances sufficiently extensive or reliable to enable us to obtain any such definite indications of the applicability of the generalizations here developed as in the case of silver chloride, but several typical examples are now being more systematically examined, and we hope to report further on this topic shortly.<sup>53</sup>

When the original solute is markedly soluble in water, the effect of the addition of other solutes containing a common ion becomes more complex, and solubility curves with minimum and maximum points may result. Such curves are discussed in the succeeding article, in connection with a study of systems of the type  $HX:HY:H_2O$ . Where the second solute contains no common ion at all (*i. e.*, in systems of the type  $RX:R'Y:H_2O$ ) the equilibria involved naturally present still greater intricacies, as the experience of previous investigators in this portion of the field serves to testify.<sup>54</sup> The satisfactory elucidation of such elaborate systems necessarily awaits the prior formulation of acceptable general rules for systems with a smaller number of variables.

<sup>49</sup> Forbes, *loc. cit.*, p. 1946.

<sup>50</sup> Glowczynski, *ibid.*, p. 172.

<sup>51</sup> Treadwell and Hall, "Analytical Chemistry," 2, 317 (1914).

<sup>52</sup> It is possible that complete precipitation might be ensured only at the expense of introducing other and more significant errors, such as adsorption of added salt by the precipitate.

<sup>53</sup> The particular series under investigation are: (a)  $AgCl$  and  $PbCl_2$  in other chloride solutions, (b) slightly soluble fluorides in  $AgF$  and  $KF$  solutions, (c) the sulfates of the alkaline earth metals in other sulfate solutions, (d) the sulfates and hydroxides of the alkaline earth metals in solutions of more soluble salts of the same metals. These are not mentioned with any intention of reserving the field, but merely to obviate possible duplication of effort.

<sup>54</sup> See the extensive work of Noyes and his collaborators, beginning in *THIS JOURNAL*, 33, 1643 (1911) and continued more recently by Harkins, *ibid.*, 38, 2679 (1916); 41, 1155 (1919).

### General Consideration of Results.

It remains to discuss, somewhat more fully than was done in the introductory section, the validity of the principle adopted as a basis for all of the comparisons here carried out, namely that compound formation between the components is the dominating factor in inducing deviations from ideality in polar solutions. The satisfactory agreement of our predictions with the facts of experiment furnishes in itself, of course, support for this view-point, indicating as it does that the disturbances due to other factors are, in general, subsidiary in their nature. In order to establish this more directly, however, the effect of these factors may here be subjected to brief analysis.

**Internal Pressure.**—Undoubtedly in many of the systems examined in the preceding pages the internal pressures of the components are very unequal. Exact data are not available, but since we know that fused salts, as a class, are far more polar than water and also vary considerably in polar character among themselves, we should expect to find solubilities much below the ideal value in many cases. It has been shown above, however, that the ideal solubility for salts of high melting point in solvents at ordinary temperatures is already practically zero, so that while the internal pressure factor may help to account for abnormally minute solubilities in isolated instances (*e. g.*, silver chloride in water) it can scarcely affect the present argument, which is based upon much larger divergences from the ideal in the opposite direction. True, the possibility exists that the internal pressure effect might increase proportionately with the solubility as compound formation becomes more extensive, but no indications that this is so are found in the present work. It appears, therefore, that under the special conditions here encountered, the internal pressure factor can be neglected.

**Heat of Fusion.**—Owing to the fact that the specific heats of substances in the solid and liquid states are not identical, the factor  $Q$  in Equation I (p. 1485) is not a true constant, even for ideal solutions, but varies with the temperature. The variation thus induced is, however, in general relatively small, and can be omitted without much error. More serious, in non-ideal solutions, is the variation in the differential heat of solution  $Q$  due to interactions between the components on admixture. As is well known, the heat effect of such interactions may be so great in certain aqueous salt solutions as to reverse the sign of  $Q$ , in which case we obtain *decreasing* solubility values with increase of temperature.<sup>55</sup>

This "heat of admixture" factor has been discussed in detail for the case of dilute solutions in an earlier article,<sup>56</sup> to which reference should be

<sup>55</sup> Most calcium salts, for example, exhibit this peculiarity in aqueous solution.

<sup>56</sup> Kendall, Booge and Andrews, *THIS JOURNAL*, 39, 2312 (1917).

made. It must be admitted here that the factor is not one which can be definitely correlated with the character of the components, and that consequently the relative positions of the various curves in a series may be very significantly affected, even to the extent of confusing the predicted order of solubilities. This is particularly the case in systems of the type  $RX:H_2O$ , in which heat of admixture variations are very pronounced, and it will undoubtedly be necessary to study the effect of this factor more intensively in the case of such systems before their solubility relationships are satisfactorily established. In systems of simpler types (*e. g.*,  $HX:RX$ ) heats of admixture are in general smaller and more uniform, being positive in sign (the addition compounds formed becoming less stable as the temperature rises) and increasing in magnitude as the extent of compound formation increases. In such series it is unlikely that the relative positions of the curves for different salts with respect to the ideal will be confused by variations in  $Q$ , consequently the comparisons carried out without taking this factor into consideration are still, in most instances, substantially valid.

**Ionization.**—With our views on the ionization of strong electrolytes at present undergoing fundamental modification, it is difficult to treat this factor rigorously. If, on the one hand, we regard the Arrhenius equation  $RX \rightleftharpoons R^+ + X^-$  as valid, and apply to it Nernst's principle of the constancy of the undissociated salt concentration in saturated solutions,<sup>57</sup> then it would follow that the solubility of a salt in an ionizing solvent should exceed the ideal value by an amount immediately calculable from the degree of ionization. For example, in the case of potassium chloride in water (p. 1489), the ideal solubility value 0.00044 at 25° would refer to the undissociated salt only, and correction for ionization<sup>58</sup> would increase it to approximately 0.0025. In other words, the change would not be large and would be in the same direction for all salts. If, on the other hand, we follow Milner and Ghosh in regarding salts as completely ionized both in the solid state and in water solution, no correction of this nature is necessary, although other factors (such as changes in the attractive forces between oppositely charged ions due to changes in the dielectric constant)<sup>59</sup> might enter into consideration.

**Association.**—In the solubility tables shown above,  $\alpha$  (the mol f of solute in the solution) has been calculated from the experiment on the assumption that

molecular types existent in the solution.<sup>60</sup> We do not know the exact association factors for the common solvents, nor the variation in these factors on addition of solute. The necessary correction, nevertheless, will be for any fixed solvent approximately proportional to the concentration of solute unless  $\alpha$  is very large,<sup>61</sup> hence it cannot affect significantly the accuracy of the comparisons here made.

Association of the solute is again a point which it is difficult to discuss at present. If the high association factors quoted for fused salts<sup>62</sup> are accepted, then it is evident that very extensive disassociation must occur as their concentration in a solution diminishes. Changes in the assumed molecular state of the solvent do not, however, change the position of the solubility curve appreciably, as has been shown in a previous article.<sup>63</sup> If, on the other hand, we regard highly polar substances, such as the common inorganic salts, as entirely ionized both in the solid state and in aqueous solution, no need to consider their association ever arises.

**Other Factors.**—The subsidiary effect of other factors (such as atomic volume, valence, etc.,) is being further studied, and will be discussed in a subsequent paper. One point, nevertheless, in connection with valence must be mentioned here. It has been assumed in comparing curves throughout this article,<sup>64</sup> for the sake of simplicity, that the addition compounds formed are of the same monomolecular type AB. Two solutes, however, of different valence character (e. g., a uni-univalent salt  $R'X$  and a uni-divalent salt  $R''X_2$ ) might be expected to give different types of addition compounds with the same solvent B (e. g.,  $R'X, B$  and  $R''X_2, B_2$ ).<sup>65</sup> Since the limiting value which  $X$  approaches at low temperatures for a perfectly stable compound of the type AB is 0.50, while for a compound of the type  $AB_2$  it is 0.33, it is obvious that the relative positions of the solubility curves will not, unless consideration is paid to the variation in type, furnish us with valid information regarding the stability of the compounds.<sup>66</sup> When it is furthermore remembered that in cases where the constituent

<sup>60</sup> For water, for example, at ordinary temperatures, a molecular weight much greater than 18.016 should be employed in accordance with the average molecular type  $(H_2O)_n$ .

<sup>61</sup> At very high concentrations of solute the relative correction necessarily diminishes. Disassociation, furthermore, will be extensive in such solutions.

<sup>62</sup> Kendall and Gross, *THIS JOURNAL*, 43, 1419 (1921).

<sup>63</sup> Booge and Andrews, *ibid.* 30, 2310 (1917). A more detailed treatment

radicals are very diverse in character several different complex addition products between the components may simultaneously be present in a solution,<sup>67</sup> it will not seem remarkable that occasional minor reversals of solubility orders are manifest in the tables presented above. It is a matter for comment, rather, that such divergences from prediction are not more frequent.

**The Electrode Potential Series.**—As a final point, the use of the electrode potential series as the basis for establishing "diversity of radicals" must be justified. Strictly speaking, instead of the experimentally determined electrode-potential values we should employ for each radical what is more fundamental and important, the real "electro-affinity." Until exact free-energy data are more numerous, however, we must be satisfied with the series as it stands, relying on the generally accepted view that it is substantially accurate.<sup>68</sup>

In view of the multiplicity of the disturbing factors discussed above, the question may pertinently be raised (as it was previously against Abegg and Bodländer) whether the generalizations deduced in this work are valid at all. The answer to the question consists in the substantial agreement of the predictions made with the facts of experiment. Criticism can, of course, be readily directed against certain discrepancies, but just as Abegg and Bodländer's general conclusions were not invalidated by the discovery of cases where their predicted solubilities were apparently in error by  $10^6$  or so, in the same way the citation of isolated abnormalities will not suffice to destroy the validity of the arguments here advanced. The justification of the present work lies in the fact that it enables us to obtain a general survey of a very important and intricate subject, with the main features involved duly emphasized. So much having been done, we can now continue more easily with the further development of the topic and with the examination of the remaining factors.

### Summary.

solubility curve

that the predominant disturbing factor is addition compound formation between the components of the solution.

In previous articles it has been established that the extent of such compound formation in any series is dependent upon the diversity in character of the constituent radicals of the components, the basis of diversity being the relative position of the variable radicals in the electrode potential series. Ionization, furthermore, has been found to increase uniformly with compound formation.

These generalizations have here been employed to predict solubility relationships in systems of various types. It has been shown that:

(a) For a fixed solute in a series of different solvents, increasing solubility and increasing compound formation proceed in parallel.

(b) For a series of different solutes of high melting point in a fixed solvent, increasing solubility and increasing compound formation also proceed in parallel at low temperatures.

Illustrations of these rules for non-aqueous and aqueous solutions have been presented which indicate their agreement with the facts of experiment.

A general discussion of solubility relationships in systems of increasingly complex nature (*e. g.*,  $RX:HX$ ,  $RX:H_2O$ ,  $RX:R'X:H_2O$ ) has been made, and the rules deduced for the simpler types of systems have been found to be applicable, to a limited extent, to the more complex types. For example:

(a) Salts of a very weak base exhibit increasing hydrate formation and increasing solubility in water as the acid radical  $X$  diverges from  $OH$ ; salts of a very weak acid show the same behavior as  $R$  diverges from  $H$ .

(b) The increase in the solubility of a difficultly soluble salt in water on addition of a second salt containing a common ion, due to complex salt formation, is dependent upon the diversity of the variable radicals.

The extension of the first of these rules to non-aqueous solutions, and the importance of the second in analytical chemistry, have been noted.

The disturbing effect of other factors upon the ideal solubility curve has been briefly examined, and the possibility of accounting for abnormalities in solubility curves.

CONDITIONS AFFECTING THE QUANTITATIVE DETERMINATION OF REDUCING SUGARS BY FEHLING SOLUTION.  
ELIMINATION OF CERTAIN ERRORS INVOLVED  
CURRENT IN METHODS.<sup>1</sup>

BY F. A. QUISUMBING AND A. W. THOMAS.

Received March 3, 1921.

The reduction of alkaline cupric solutions by certain sugars has been extensively utilized in qualitative and quantitative analyses of saccharine mixtures since 1841, when Trommer<sup>2</sup> first introduced alkaline copper sulfate as a reagent to distinguish dextrose from sucrose.

Barreswil<sup>3</sup> improved Trommer's reagent by the addition of potassium tartrate which prevented the precipitation of cupric hydroxide, thus increasing the stability of the reagent. Fehling<sup>4</sup> worked out the details of the quantitative method, giving some stoichiometrical equivalents between copper and dextrose. The ratio of 1 molecule of dextrose to 5 of copper was regarded constant by Fehling and was so employed until Soxhlet<sup>5</sup> showed that the ratio was not constant, but varied according to the amount of copper in solution.

The literature relative to modifications of methods of sugar analysis is so voluminous that a detailed discussion cannot be given here. Many of the modifications are described by Browne.<sup>6</sup>

Despite numerous attempts to improve upon the original methods, there is none which will give perfect quantitative results in the analysis of mixtures of common sugars. The errors involved are (1) reducing action of sucrose, (2) "blank" or auto-reduction of Fehling solution, including all modifications of same, and (3) lack of exact control of temperature.

A study of the reducing action of sucrose on Fehling's solution and the effect of the presence of sucrose upon reducing sugars with a view of eliminating the use of empirical formulas and correction tables as a means of correcting for the effect of sucrose is of timely interest.

If the necessity of running "blank" tests to determine the amount of auto-reduction of the Fehling solution (which may be as much as 5 mg.

<sup>1</sup> Part of the thesis submitted by F. A. Quisumbing in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Faculty of Pure Science of Columbia University, 1921.

<sup>2</sup> Trommer, *Ann.*, 39, 360 (1841).

<sup>6</sup> Browne, "Handbook of Sugar Analysis," John Wiley & Sons, 1912.

of cuprous oxide and is not constant) could be dispensed with, it is admitted that greater accuracy and speed would be realized.

In all methods the reaction between reducing sugars and the complex cupric compound is carried out at the indefinite temperature obtained by heating in a bath of boiling water, or boiling the mixture directly over a flame. It is evident that since the amount of reduction varies with the temperature and time of digestion, errors are unavoidable due to changes in barometric pressure. Further, the methods involving direct boiling of the mixture are subject to an additional lack of accuracy due to the difficulty in determining exactly when the solution begins to boil. Apart from the inaccuracy of this sort of procedure, the manipulator is obliged to give his constant attention during the boiling.

The purpose of this investigation is to establish conditions for the use of a Fehling solution in the quantitative analysis of common sugars such that the errors due to atmospheric pressure fluctuations and temperature of digestion, difficulty in observation of exact time of boiling, surface oxidation, auto-reduction of Fehling solution, and reducing action of sucrose might be eliminated or reduced to a minimum.

### Sugars Used.

Solutions for measurement of optical rotation were made in all cases by dissolving 5 g. of the sugar in distilled water and adjusting to 100 cc. at 25°. The solutions were allowed to stand until optical equilibrium had been attained before polarization.

A Schmidt and Haensch polarimeter, sensitive to 0.01° angular scale was employed, the solutions in 2 dm. tubes being maintained at 25°  $\pm$  0.01°, by use of the thermostat described by Nelson and Beegle.<sup>7</sup>

Unpurified sodium flame, and the light of a mercury vapor lamp passed through Wratten No. 74 filter, giving a wave length,  $\lambda = 546\mu\mu$ ,<sup>8</sup> were used as sources of light.

**Sucrose.**—Bureau of Standards, Sample No. 17. Analysis showed: moisture 0.003%; ash, 0.003%. No reducing action was shown by 400 mg. of this sugar on Fehling solution at 80° during 30 minutes. Specific rotatory power,  $[\alpha]_{\lambda=546}^{25} = 78.200^\circ$ ;  $[\alpha]_D^{25} = 66.405^\circ$ .

**Dextrose.**—A specimen of the Corn Products Refining Company's c. p. Dextrose, was purified according to the Bureau of Standards method.<sup>9</sup> Analysis of this pure sample showed: moisture, 0.150%; ash, 0.003%. Specific rotatory power,  $[\alpha]_{\lambda=546}^{25} = 62.021^\circ$ ;  $[\alpha]_D^{25} = 52.480^\circ$ .

**Levulose.**—A white crystalline specimen kindly furnished by Prof. J. M. Nelson was recrystallized from conc. acetic acid solution as recommended by Hudson and Dale<sup>10</sup> for dextrose. The sample after drying *in vacuo* over saturated sodium hydroxide solution showed: moisture, 0.002%; ash, 0.060%. Specific rotatory power,  $[\alpha]_{\lambda=546}^{25} = -105.30^\circ$ ;  $[\alpha]_D^{25} = -89.40^\circ$ .

<sup>7</sup> Nelson and Beegle, *THIS JOURNAL*, 41, 559 (1919).

<sup>8</sup> W. C. Vosburgh, *ibid.*, 42, 1698 (1920).

<sup>9</sup> Bur. Standards, *Circ.*, 44, 92 (1919).

<sup>10</sup> Hudson and Dale, *THIS JOURNAL*, 39, 320 (1917).

**Invert Sugar.**—The invertase method of preparation was tried and found unsatisfactory for our purpose because of the formation of an insoluble copper compound when the residual invertase was heated with Fehling solution. This is the so-called "copper yeast gum" (Salkowski<sup>11</sup>), also mentioned by Nelson and Born.<sup>12</sup> For these reasons the invert sugar solution was prepared by mixing equal numbers of molecules of dextrose and levulose. Specific rotatory power,  $[\alpha]_{\lambda=546}^{25} = -21.50^\circ$ ;  $[\alpha]_D^{25} = -18.39^\circ$ .

**Lactose.**—Squibb's pure lactose was dissolved in boiling distilled water and when cold, a mixture of equal volumes of ether and alcohol was added. The lactose crystallized from this solution, washed with alcohol and ether, was dried *in vacuo* at  $70^\circ$ . This dried material was ground and dried further at  $100^\circ$  for 4 to 5 hours. Analysis showed it to contain: moisture (loss at  $125^\circ$  to  $130^\circ$ ), 5.22%; ash, 0.03%. Specific rotatory power,  $[\alpha]_{\lambda=546}^{25} = 61.36^\circ$ ;  $[\alpha]_D^{25} = 52.90^\circ$ .

**Maltose.**—This sugar was prepared from Lintner<sup>13</sup> soluble starch by saccharification of the starch with highly purified malt amylase kindly furnished by Professor H. C. Sherman. The product of the saccharification was fermented by a pure culture of *Saccharomyces Ludwigii* to remove fermentable sugars other than maltose. Upon completion of fermentation, the solution was heated in an autoclave, cooled and the dextrins precipitated by alcohol. The filtrate was evaporated *in vacuo* to a thin syrup, which upon inoculation with a few maltose crystals yielded a crop of crystals which were recrystallized from hot 95% alcohol, using acid-purified cocoanut charcoal as decolorizing agent. This maltose was dried *in vacuo* at  $60^\circ$  for 4 hours, ground to powder and further dried at  $90^\circ$  for 10 hours. The final product contained: moisture, 5.05%; ash, 0.02%. Specific rotatory power,  $[\alpha]_{\lambda=546}^{25} = 153.75^\circ$ ;  $[\alpha]_D^{25} = 131.25^\circ$ .

### Atmospheric Pressure and Temperature of Boiling.

Irregularity of results due to the effect of fluctuations of atmospheric pressure on temperature of boiling has been reported by several investigators.<sup>14</sup> A series of experiments conducted in this laboratory at different times of the year under barometric pressures varying from 753 mm. to 760 mm. lend support to the above findings. The reducing power of 100 and of 150 mg. of dextrose determined by the 2-minute boiling over a flame and the 12-minute digestion in boiling water varied 2% between the atmospheric pressures mentioned.

It is apparent that variation in boiling point due to ordinary changes in atmospheric pressure and also due to location of laboratories at different altitudes may seriously affect the accuracy of results obtained by the reduction methods in common use.

To overcome the uncertainties of temperature in all experiments cited herein, a thermostat was used in which water served as the liquid medium for temperatures below  $90^\circ$ , and rapeseed oil for higher temperatures.

### Influence of Temperature and Time of Heating.

The results of a series of experiments to determine the most suitable temperature and length of time of heating for the oxidation of the sugars by a Soxhlet-Fehling solution are plotted in Figs. 1 and 2. The solution consisted of 50 cc. of mixed Soxhlet-Fehling<sup>15</sup> solution and 50 mg. of glucose, the volume being adjusted to 100 cc. with distilled water.

Upon critical examination of the curves in Figs. 1 and 2, it is seen that temperature and time of heating exert a great influence on the oxidation of dextrose. Reduction increases with rise of

REDUCTION BY GLUCOSE AT DIFFERENT TEMPERATURES

Fig. 1.

CURVES SHOWING THE INFLUENCE OF TIME ON REDUCTION BY GLUCOSE

Fig. 2.

temperature and it appears complete at temperatures below 90° after an hour's heating. At temperatures above 100° there is an appreciable increase in reduction which may be due to auto-reduction of Fehling solution.

The curves in Fig. 3 show that Soxhlet-Fehling solution is reduced at high temperatures when no sugar is present. The detection of cuprous oxide in so-called traces in the "blanks" by

<sup>15</sup> Soxhlet's formula: (A) 34.639 g. of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  in 500 cc. of solution; (B) 173 g. of Rochelle salt, and 51.6 g. of NaOH in 500 cc. of solution.

methods of 2 minutes boiling over a flame or heating in boiling water is due to this auto-reduction of Fehling solution. Attention is called to the absence of such auto-reduction at 80° for periods of heating up to 30 minutes, and furthermore that at this temperature there is but slight formation of cuprous oxide even after heating for 1 hour.

Fig. 3.

is but slight formation of cuprous oxide even after heating for 1 hour.

### Reducing Action of Sucrose on Fehling Solution.

A study of the effect of sucrose in the presence of reducing sugars has been made by Maquenne,<sup>16</sup> Pellet,<sup>17</sup> Saillard,<sup>18</sup> Browne<sup>19</sup> and others, but no definite efforts have been made to eliminate its reducing action on Fehling solution.

Experiments show that when the current methods of heating are used, the error in the glucose and invert sugar determinations, when sucrose is present is considerable. Browne<sup>20</sup> gives an empirical formula for the correction of errors due to reducing action of sucrose on glucose. Meissl and Hiller<sup>21</sup> give tables of factors for calculating copper to invert sugar for different ratios of sucrose to invert sugar. Munson and Walker<sup>22</sup> give tables for the determination of invert sugar and lactose in the presence of sucrose.

The inadequacy of the use of these tables, factors for correction, empirical formulas and other unnecessary calculations involved, led to the following study of the comparative action of sucrose on Fehling solution with the view of establishing the best conditions by which the reducing action of sucrose could be entirely eliminated or reduced to a minimum.

<sup>16</sup> Maquenne, *Compt. rend.*, 162, 207, 145 (1916); 161, 617 (1915).

<sup>17</sup> Pellet, *Ann. Chem. Anal.*, 20, 169 (1915); *Bull. Assoc. Chem. suc. dist.*, 31, 183 (1913-14).

<sup>18</sup> Saillard, *Compt. rend.*, 161, 591 (1915); *J. Fabr. suc.*, 56, 1 (1915).

<sup>19</sup> Browne, *THIS JOURNAL*, 28, 439 (1906).

<sup>20</sup> Browne, "Handbook of Sugar Analysis," 1912, p. 428.

<sup>21</sup> Meissl and Hiller, *Z. Ver. Deut. Zuckerind.*, 39, 735 (1889).

<sup>22</sup> Munson and Walker, *THIS JOURNAL*, 28, 663 (1906).

From the curves in Fig. 4 it is apparent that the reducing action of sucrose is considerable when current methods are used. The amount of copper reduced mounts rapidly with increase in concentration of sucrose.

The reducing values plotted in the above figure were all corrected for "blank" reductions.

Fig. 4.

### Selection of Conditions for Reduction.

If it were feasible to determine when the process of reduction is complete, that point would be the most appropriate one at which to terminate the treatment, but when the time element is considered, it does not matter whether the terminal point is reached for the purpose of testing an analytical method. By selecting a set of standardized conditions such that the amount of reduction obtained is sharply defined at a selected point, that point may successfully be used as a terminal point. Upon critical study of the curves in Figs. 2 and 3, the conditions of 80° and 30 minutes appear to be most ideal, because (1) Fehling solution at this temperature and time of heating does not give a "blank" reduction; and (2) beyond 30 minutes heating at 80° the curve rises very slightly. This point can therefore be safely called the "terminal point." Temperatures other than 80° might have been selected, but a lower temperature would require a longer time of heating to give a reasonable amount of copper for quantitative determination, and at higher temperatures the difficulty of accurately maintaining the temperature of the bath interferes with the accuracy of short-time digestions.

Objection may be raised that 30 minutes' reduction involves too much time for the analysis, but experience has proved that when sets of 7 samples

are run under these conditions, the reducing power of a sample can be determined within 8 to 10 minutes from the time the sample is placed in the bath to the completed washing of the precipitated cuprous oxide.

A great advantage claimed for this method over the procedure of boiling over a flame is that continuous observation to determine the time boiling is not required. Furthermore, this method offers an important improvement over the current methods in the complete elimination of auto-reduction of Fehling solution; and as shown in Fig. 4, the presence of as much as 425 mg. of sucrose has no effect on the accuracy of the process. We find also that a long time of heating produces a coarse granular cuprous oxide which is easily washed and removed from the beaker without the aid of a rubber "policeman."

### Apparatus and Procedure.

**Thermostat.**—A 50-liter constant-temperature bath, similar to the one described by H. C. Sherman and A. W. Thomas,<sup>23</sup> and J. M. Nelson and F. M. Beegle<sup>7</sup> was constructed. The temperature was maintained at  $80^{\circ} \pm 0.1^{\circ}$ . Excessive evaporation of the water was prevented by the addition of 2 or 3 drops of colorless paraffin oil.

**Procedure.**—When the bath had attained proper temperature, a 350-cc. beaker containing the solution to be tested was placed in it, supported on an iron ring, so that the levels of the liquid in the container and the water in the bath were practically identical. Occasionally the beaker was shaken and the solution rotated to ensure thorough mixing. At the end of the desired time of heating, the beaker was removed, and the solution containing the precipitated cuprous oxide filtered through a mat of asbestos in a Gooch crucible. The precipitate was washed with warm water, then dissolved with 10 to 20 cc. of 16 *N* nitric acid, and copper determined either by Beans and Stillman's<sup>24</sup> electrolytic method or E. C. Kendall's<sup>25</sup> modified iodide method.

### Fehling Reagent.

As a result of Nef's<sup>26</sup> work we know that the sugar molecule in the presence of Fehling solution undergoes oxidation, reduction, condensation or further decomposition giving rise to a great multiplicity of aldehydes and acids as end products, the kinds, as well as amounts of which, vary with concentration of sugar and of alkali used.

<sup>23</sup> Sherman and Thomas, *THIS JOURNAL*, 37, 623 (1915).

<sup>24</sup> J. W. Stillman, "New Direct Method for the Electrolytic Determination of Copper," *Dissertation*, Columbia Univ., 1920.

<sup>25</sup> Kendall, *THIS JOURNAL*, 33, 1947 (1911).

<sup>26</sup> Nef, *Ann.*, 357, 214 (1907); 376, 1 (1910); 403, 204 (1914).

**Influence of the Nature of the Alkali.**—The nature and amount of alkali in Fehling solution influence both reduction and the physical character of the copper oxide formed. Sodium hydroxide and potassium hydroxide solutions of equivalent concentrations give practically the same reduction with dextrose and invert sugar. Glendinning<sup>27</sup> finds that maltose shows a higher reducing power when potassium hydroxide is substituted for sodium hydroxide in Fehling solution. Kjeldahl<sup>28</sup> studying the effect of different strengths of sodium hydroxide solution upon reduction, found that between limits of 0.5 to 2 *N* sodium hydroxide solution, the variation was not more than 1% with glucose, while with maltose and lactose there was a wide variation.

It is our experience that Fehling solution containing sodium hydroxide gives a more satisfactory precipitation than when potassium hydroxide or the carbonates are used. The curves in Fig. 5 illustrate the influence

Fig. 5.—The influence of different alkalis in Fehling solution on the oxidation of glucose.

of kind and concentration of alkali upon the oxidation of glucose by Fehling solution.

**Influence of Concentration of Alkali.**—According to Fig. 6 the most effective alkalinity of Fehling solution is 1.6 *N* in terms of sodium hy-

<sup>27</sup> Glendinning, *J. Chem. Soc.*, 67, 999 (1895).

<sup>28</sup> Kjeldahl, *Compt. rend. trav. Laboratoire Carlsberg*, [1] 4, (1895).

dioxide. This alkalinity has also been found best by Kjeldahl<sup>28</sup> and Brown, Morris and Millar,<sup>29</sup> when reduction was carried on in a boiling-water-bath. Fehling solution, of this alkalinity corresponds to 65 g. of sodium hydroxide in 500 cc. of the alkaline tartrate solution.

Fig. 6.—The influence of different concentrations of alkali in Fehling solution on the oxidation of sugars.

The curves show that the concentration of hydroxyl ions influences the rate and amount of oxidation of the sugars. The amount of copper reduced increases with increasing concentration of hydroxyl ions up to a certain point, where oxidation appears to be at its maximum, and from that point further increase in hydroxyl ions tends to decrease reduction. The most plausible explanation for this is that the decrease in reduction is due to the formation in large quantities of compounds of lower reducing power. The same phenomenon is exhibited regardless of the nature of alkali. Greater decomposition of the sugar is more apparent with lactose and maltose.

**The Effect of Varying the Amount of Copper Sulfate in Fehling Solution.**—To determine this effect a test solution consisting of 50 cc. of Fehling solution containing various amounts of copper sulfate, 3.2 g. of sodium hydroxide, 8.65 g. of the sodium potassium tartrate and 100 or 200 mg. of the sugar was used. The total volume of the solution was adjusted to 100 cc. with distilled water in each case.

<sup>29</sup> Brown, Morris and Millar, *J. Chem. Soc.*, 71, 96 (1897).

TABLE I.

OXIDATION OF REDUCING SUGARS BY FEHLING SOLUTION CONTAINING VARIOUS AMOUNTS OF COPPER SULFATE, AT 80° FOR 30 MINUTES.

Wt. of Cu in 50 cc. Mg.	Ratio of NaOH to Cu by weight.	Reduction in terms of mg. of Cu.						Blank.

TABLE II.

OXIDATION OF DEXTROSE IN THE PRESENCE OF SUCROSE BY FEHLING SOLUTION CONTAINING VARIOUS AMOUNTS OF COPPER SULFATE.

Reduction By Dextrose Alone.

Wt. of Cu in Fehling sol. Mg.	Reduction in terms of mg. of Cu.			
	Mg. of dextrose in 10 cc. of solution.			Blank.
	5 mg.	50 mg.	95 mg.	
525	17.8	161.0	297.8	0
630	17.6	160.8	299.2	0.3
840	19.2	157.2	297.2	0.9
1050	18.5	155.8	291.3	3.0
1260	17.5	151.8	287.4	3.5

REDUCTION OF DEXTROSE IN THE PRESENCE OF SUCROSE.

Reduction in terms mg. of Cu.

	5 mg. Dextrose. 50 mg. Dextrose. 95 mg. Dextrose.		
	95 " Sucrose. 50 " Sucrose. 5 " Sucrose.		
	5 mg. Dextrose. 95 " Sucrose.	50 mg. Dextrose. 50 " Sucrose.	95 mg. Dextrose. 5 " Sucrose.
525	17.8	161.0	297.6
630	20.2	161.0	299.4
840	21.1	159.0	296.8

Upon examination of Tables I and II, the most suitable ratio is seen to be from 5 to 6 of sodium hydroxide to 1 of copper by weight. In other words, with the alkalinity of 1.6 *N* (3.2 g. of sodium hydroxide per 50 cc. of mixed reagent), 0.525 to 0.630 g. of copper gives the most satisfactory reduction. It is also interesting to note that with increasing concentration of copper sulfate, total reduction is decreased, while auto-reduction of the solution is increased. Furthermore, Table II shows that in the presence of sucrose, increasing the concentration of copper sulfate tends to increase reduction. It seems therefore that concentration of copper has a direct bearing on the decomposition of sucrose. If enough reducing sugar is present to precipitate nearly all of the copper in Fehling solution, the presence of sucrose plays no part in the reduction.

**The Effect of Varying the Amount of Sodium Potassium Tartrate in the Presence of Constant Amounts of Alkali and Copper Sulfate.**—The test solution consisted of 25 cc. of copper sulfate solution containing 525 mg. of copper (as cupric sulfate), 3.2 g. of sodium hydroxide, 100 mg. of the sugar and various amounts of tartrate. The volume of each solution was made up to 100 cc. with distilled water.

A saturated solution of sodium potassium tartrate was prepared from a commercial Rochelle salt (Highest Purity), and filtered. To the clear solution, 95% alcohol was added with constant stirring, and the salt was allowed to crystallize. The crystals were washed with alcohol, and dried in an oven at 50° for 15 hours, and then at 60° to 65° for 10 hours. The salt as analyzed contained 4 molecules of water of crystallization.

TABLE III.  
INFLUENCE OF CONCENTRATION OF ROCHELLE SALT.

Weight of Rochelle salt.	Mg. of copper reduced.			
	Dextrose.	Levulose.	Lactose.	Maltose.
G.				
7.96	159.0	155.4	112.3	90.3
8.65	159.5	154.2	112.9	92.5
11.38	158.8	155.3	113.1	93.0
15.84	157.7	154.0	112.5	92.6
17.30	155.3	155.0	112.6	92.8

Table III shows that there is no material effect of increasing the concentration of the tartrate beyond that called for by the Soxhlet-Fehling formula. The formation of the complex cupric tartrate ion is assured by the presence of 8.65 g. of Rochelle salt in 50 cc. of the mixed Fehling solution. Less than this amount appears to give less reduction for lactose and maltose. The reduction by dextrose decreases with increasing concentration of the tartrate while with levulose there is no appreciable effect of increasing amounts of tartrate upon the reduction.

**Photosensitiveness and Keeping Quality.**—The photosensitiveness of Fehling solution as evidenced by the precipitation of cuprous oxide upon exposure of the solution to light was noticed by Fehling<sup>4</sup> and numerous other investigators<sup>30</sup> have confirmed this.

Our experiments show that 50 cc. of mixed Fehling solution exposed to direct sunlight will give traces of cuprous oxide precipitate within 10 to 20 hours, while if kept in the dark, or in opaque bottles, or in ray-filter solutions such as potassium dichromate, or acidified quinine sulfate, decomposition does not take place until after a month or longer. 50 cc. of mixed Fehling solution exposed to direct sunlight will be completely

<sup>30</sup> Eder, *Sitzungsber. Akad. Wiss., Wien*, 92, 344 (1885); through *J. Phys. Chem.*, 17, 204 (1913); Byk, *Z. physik. Chem.*, 49, 659, 679 (1904); Leighton, *J. Phys. Chem.*, 17, 204 (1913).

decolorized after 2 months, showing then only a slight amount of copper present.

Fehling solution as ordinarily prepared shows a slight tendency to auto-reduction.

Munson and Walker<sup>31</sup> contended that unless the spontaneous reducing power of the alkaline tartrate solution is determined and allowed for, the results obtained will be considerably too high. In their original article<sup>22</sup> Munson and Walker gave a series of figures showing the reducing power of their alkaline tartrate solution from day to day during the course of their investigation. The results varied from  $-0.8$  to  $+1.6$  mg. of cuprous oxide.

Our experiments with Fehling solutions of varying copper, tartrate and alkali content show conclusively that the reducing power of the solutions is not entirely due to impurities of the alkaline tartrate solution as generally claimed, but to a great extent to the method of heating. Samples of Fehling solution prepared according to the formula given in page 1520, showed no reducing power when heated at  $80^{\circ}$  for 30 minutes, *i. e.*, no "blank," after they had been kept in the dark for 5 months; but, if reduction was carried out according to Munson and Walker's method, the solutions gave a considerable precipitate, which varied from 1.5 to 4.0 mg. of copper.

### Colloidal Cuprous Oxide.

When a reducing sugar is treated with an alkali, a series of degradation products is formed, and these are responsible for the reduction of the cupric salt. The cuprous oxide precipitate that comes down first in the hydrate form has different degrees of dispersion. The different colors of the same chemical compound,  $\text{Cu}_2\text{O}$ , when in the colloidal state, are claimed by Svedberg<sup>32</sup> and Wo. Ostwald<sup>33</sup> to be nothing more than the color changes coincident with the gradual increase of the size of the particles, the red being the largest.

Experiments performed in this laboratory show that the concentration of the reducing substance, nature of the alkali, and the degree of alkalinity of the latter, temperature and time of heating influence the production and physical character of cuprous oxide. The "colloidal" particles are produced even at 6 *N* alkalinity with the carbonates, while with the alkali hydroxides, the same dispersions are noticeable only at concentrations below 0.5 *N*. Reduction at high temperatures augments the production of the "colloidal" copper oxide. Low temperature and a fairly high con-

<sup>31</sup> Munson and Walker, *THIS JOURNAL*, 29, 541 (1907).

<sup>32</sup> Svedberg, "Herstellung Kolloider Lösungen," Steinkopff, 1920.

<sup>33</sup> Wo. Ostwald, *Kolloidchem. Beihefte*, 2, 409 (1911).

centration of alkali in Fehling solution increase the size characteristic of the red cuprous oxide.

### Surface Oxidation.

The size and shape of receptacles in which the mixture of Fehling solution and sugars are heated have an effect on the amount of copper reduced. Also the nature of the material of which the receptacle is made has an influence upon the velocity of deposition of cuprous oxide.<sup>28,34,35</sup>

While an appreciable loss of cuprous oxide is known to result from surface oxidation, no attempt has been made to correlate surface area of the reagent exposed to the walls of the glass container and reduction. To get definite figures for such relationship, the following experiments were made. They were performed in beakers where the surface of the reagent was exposed to direct action of the air. The solution consisted of 200 mg. of the sugar and 50 cc. of Fehling solution, made up to 100 cc. with distilled water.

Table IV shows that reduction is directly proportional to lateral area of liquid exposed to the glass and inversely proportional to surface area of liquid exposed to the air. That is, the more surface area of the liquid exposed to the air, the less the amount of copper reduced. Boiling for 2 minutes over a flame gives reduction which varies to the extent of 5.8 mg. of copper with beakers in which the surface area of the liquid exposed to the air ranged from 43.7 to 85.6 sq. cm. Heating for 20 minutes in boiling water gives a difference of 3.2 mg. and for 30 minutes in water at 80°, 2.9 mg. It should be observed that in all these three methods of heating 350 and 550 cc. beakers gave practically the same reduction, although the surface areas of the liquid exposed to the air differed by 13.3 sq. cm. This is due to the fact that their *total surface areas* ( $2\pi rh + \pi r^2$ ) are equal.

A second series of experiments was planned in order to study this relationship further. The solutions consisted of 100 mg. of dextrose and 50 cc. of Fehling solution, made up to 100 cc. with distilled water. In (1) the liquid was covered with a layer of toluene, (2) the beakers were covered with watch glass, and in (3) the liquid was left exposed to the air. Copper was determined electrolytically.

Table V shows that when the action of air is excluded, reduction is proportional not to *total* but to *lateral* area of liquid exposed to the glass; that is, the higher the column of liquid exposed to the glass surface, the more cuprous oxide is precipitated. It appears that the most plausible explanation for this phenomenon is that reduction is accelerated more along the sides than at the bottom of the container because as the precipitate

<sup>34</sup> Urecht, *Bér.*, 15, 2687 (1882).

<sup>35</sup> Kendall, *THIS JOURNAL*, 34, 317 (1912).

drops down from the sides to the bottom, the layer of cuprous oxide thus formed tends to cut down the accelerating effect of the glass surface at the bottom, and leaves a free surface along the sides for catalytic action. The table also shows that the amount of cuprous oxide lost due to surface oxidation is proportional to the area of liquid exposed to the air.

TABLE IV.

EFFECT OF SURFACE AREA OF LIQUID EXPOSED TO THE AIR AND LATERAL AREA OF LIQUID EXPOSED TO THE GLASS ON THE AMOUNT OF COPPER REDUCED.

(200 Mg. of Dextrose Used in Each Case.)

Receptacle.	Cc.	Diameter. Cm.	Height of column of liquid. Cm.	Lateral area liquid exposed to glass. Sq. Cm.	Surface area of liquid exposed to air. Sq. Cm.	Methods of heating.		
						2 min. boiling over a flame.	20 min. heating in boiling water.	30 min. heating in water in 80°.

The figures represent averages of duplicate determinations which varied not more than 0.7 mg. of Cu.

TABLE V.

(100 Mg. of Dextrose Used in Each Case.)

Beaker.	Diameter.		Height of column of liquid.	Lateral area of liquid exposed to glass.	Surface area of liquid exposed to air.	(1) Covered with toluene.	(2) Covered with watch glass.	(3) Uncovered.	Loss. (1) — (3).
Cc.	Cm.	Cm.	Sq. Cm.	Sq. Cm.					
1000	12.0	1.7	63.2	111.6	196.7	196.3	191.6	5.1	
350	8.5	3.5	92.2	56.8	198.7	198.2	196.2	2.5	
140	6.25	5.5	110.8	36.0	199.4	200.9	198.8	0.6	

The figures represent averages of duplicate determinations which varied not more than 0.4 mg. of Cu.

The effect of surface oxidation was further investigated by adding to definite weights of chemically pure cuprous oxide, 50 cc. of Fehling solution and making the total volume of the solution up to 100 cc. with distilled water, and transferring to 350 cc. beakers of same diameters. One cc. of toluene was added to each. After the mixtures had been heated for 30 minutes in water at 80°, the cuprous oxide was filtered off, washed and copper determined electrolytically.

	Covered with toluene. Mg.	Covered with watch glass. Mg.	Uncovered. Mg.	
Weight of $\text{Cu}_2\text{O}$ used.....	147.9	234.2	230.6	239.6
" " " recovered.....	147.8	234.0	227.2	237.0

Cuprous oxide used and recovered was calculated from the weight of copper determined electrolytically.

These experiments show that the loss of cuprous oxide due to surface oxidation can be obviated by either covering the liquid with some inert liquid such as toluene, or by covering the beaker with a watch glass. The latter serves to prevent evaporation of the liquid as well as surface oxidation. Kjeldahl<sup>28</sup> eliminated this error by use of an atmosphere of hydrogen or of oxygen-free illuminating gas. Although Kjeldahl's method undoubtedly gives more nearly the true reduction, the inconveniences attending such manipulation would preclude its general use. Covering the beaker with a watch glass approximates quite as well the true reduction as the other expedients suggested, and, of course, is preferable because of its simplicity.

### Mutual Effect of Sucrose and Reducing Sugars.

Earlier in this discussion it was noted that under the newly proposed conditions the presence of as much as 425 mg. of sucrose had no reducing action on the modified Fehling solution.

The reducing action of sucrose was further investigated by running reductions with different mixtures of sucrose and reducing sugars. The effects are shown in the tables following. In these tables the amounts of reducing sugar are to be found in the first column and the weights of sucrose mixed with the different amounts of reducing sugar are given in the top horizontal line. The figures given in the second column are the amounts of cuprous oxide precipitated by the respective amounts of reducing sugar, expressed in terms of milligrams of copper, while in the remaining columns is given excess reduction caused by the presence of the sucrose.

TABLE VI.  
REDUCTION BY MIXTURES OF SUCROSE AND DEXTROSE.

It is apparent that the reducing action of sucrose in the presence of dextrose is negligible at concentrations below 400 mg. The greater the proportion of dextrose, the less the action of sucrose; that is, the reducing action of sucrose upon Fehling solution is proportional to concentration of sucrose and amount of copper left unreduced. If enough dextrose is present to precipitate nearly all of the copper in Fehling solution, reduction due to sucrose is slight.

Upon examination of the reducing values of sucrose and dextrose, it appears that for certain concentrations of the two sugars, total reduction is the sum of the two; while at certain concentrations, it is less. Past a certain point, the phenomenon reverses, and dextrose instead of acting as a protector, actually accelerates the decomposition of sucrose. This change in reduction of sucrose decreases however with increasing amounts of dextrose. The decrease in reduction at certain points indicates probably the formation of complex copper sodium sucrates, the dissociation constants of which decrease in the presence of increasing concentrations of the sugar, and this diminishes the alkalinity and concentration of ionizable copper of the reagent. It is obvious therefore, that reduction by sucrose is not entirely a matter of hydrolysis of its molecule, but is a direct function of the molecule itself.

Fig. 7.

Table VII shows that the action of sucrose on levulose is negligible at concentrations below 300 mg. Levulose has an accelerating action upon the decomposition of sucrose, this action being greatest between 40

and 160 mg. of levulose, while in the presence of more than 160 mg. of levulose this phenomenon is not manifested, and as in the case of dextrose, when sufficient reducing sugar is present to precipitate the greater part of the copper, the reducing action of sucrose decreases.

These tables bring out certain effects of the various reducing sugars in the presence of sucrose which are difficult to interpret. The presence of as much as 400 mg. of sucrose does not affect the accuracy of determination of dextrose, while in the case of levulose the presence of 400 mg. of sucrose will cause no appreciable error provided 120 mg. or more of levulose is present. When less than this amount of levulose is present, then not more than 200 mg. of sucrose is permissible for accurate results. A protective action of invert sugar when present in large amounts is shown when mixed with 500 mg. of sucrose, and although this fails to a certain extent when from 1 to 2 g. of sucrose is present, yet the total reduction of the mixture of sugars is less than that of both taken separately.

Maltose and lactose show the odd effect of catalyzing the reduction by sucrose when this sugar is mixed with them. The action of maltose is more marked than that of lactose. It will be noted that in the presence of lactose, not more than 200 mg. of sucrose may be present if the true reducing power of the lactose is desired, and with maltose the amount of sucrose present must not exceed 100 mg. for analyses of high degree of accuracy.

### Preparation of Proposed Modification of Fehling Solution.

1. **Copper Sulfate Solution.**—The crystals of c. p. copper sulfate were washed free from dust, etc., with distilled water and dissolved in hot water to make a saturated solution and filtered. The copper was determined electrolytically and the solution diluted so that 25 cc. of it contained 525 mg. of copper or 41.2 g. of cupric sulfate pentahydrate in 500 cc. of the solution.

2. **Alkaline Tartrate Solution.**—*Sodium hydroxide.* A saturated solution was prepared from sodium hydroxide (purified by alcohol) and let stand for several days until the insoluble carbonates and other impurities had settled out. The clear solution was siphoned off and its alkalinity established by titration with standard acid.

*Crystallized Rochelle salt*, 173 g. (highest purity), was dissolved in water in a 500-cc. graduated flask and the calculated amount of sodium hydroxide solution added, so that 500 cc. of this alkaline tartrate solution contained exactly 65 g. of sodium hydroxide.

It is absolutely necessary that sodium hydroxide for the alkaline tartrate solution should be prepared as described above, because purity

of the reagent and exact concentration of the alkali in Fehling solution has such a decided influence on the oxidizing power of the reagent. Weighing of sodium hydroxide sticks is not recommended.

### General Procedure.

Measure accurately 25 cc. each of the copper sulfate and alkaline tartrate solutions into a 400 cc. Pyrex or Bohemian glass beaker, the diameter of which is about 9 cm. Add 50 cc. of sugar<sup>36</sup> solution making a total volume of 100 cc. Cover the beaker with a watch glass and place the beaker in a water-bath which is maintained at 80°. After exactly 30 minutes' digestion, filter the cuprous oxide by suction through a mat of asbestos in a Gooch crucible. Wash the precipitate in the usual manner and determine the copper by one of the methods discussed at the end of this paper. From the weight of copper or cuprous oxide obtained, find the corresponding weight of reducing sugar from Table XIII or calculate it by means of the equations given below.

### Sugar Table.

Figures in the sugar table were calculated from the equation  $y = a + bx + cx^2$ , by method of least squares,<sup>37</sup> where  $y$  = mg. of sugar and  $x$  = mg. of copper.

$$b = \frac{\Sigma (x^4) \Sigma (xy) - \Sigma (x^3) \Sigma (x^2y)}{\Sigma (x^2) \Sigma (x^4) - [\Sigma (x^3)]^2}$$

$$c = \frac{\Sigma (x^2) \Sigma (x^2y) - \Sigma (x^3) \Sigma (xy)}{\Sigma (x^2) \Sigma (x^4) - [\Sigma (x^3)]^2}$$

Dextrose.....	$y = 0.474x + 0.000115x^2$
Levulose.....	$y = 0.526x + 0.000078x^2$
Lactose.....	$y = 0.813x + 0.000003x^2$
Maltose.....	$y = 0.990x + 0.0000005x^2$
Invert Sugar...	$y = 0.504x + 0.0000870x^2$

<sup>36</sup> Weights of the sugars to be taken for analysis. For dextrose, levulose and invert sugar, take 50 to 150 mg; for lactose and maltose, take 100 to 300 mg. These weights of sugars will reduce about 100 to 350 mg. of copper. In the presence of sucrose, the weight of sample to be taken for analysis can be judged by a preliminary test. In mixtures of sucrose and dextrose up to 400 mg. of sucrose will not influence the accuracy of the determination of dextrose. For mixtures of sucrose and levulose (or invert sugar) not more than 200 mg. of sucrose may be present, unless more than 160 mg. of reducing sugar is present, in which case as much as 400 mg. of sucrose will not affect the result. With sucrose-lactose mixtures the maximol permissible amount of sucrose is 200 mg. and 100 mg. in sucrose-maltose mixtures. In any case, where the composition of the sample is unknown, there will be no danger of error due to the presence of sucrose, if not more than 100 mg. of sample is taken. This allows for the possible presence of maltose.

TABLE XII.—REDUCING RATIOS.

Showing the Reducing Ratios of Levulose, Invert Sugar, Lactose and Maltose by the New Method.

Copper. Mg.	Dextrose. Levulose.	Dextrose. Invert sugar.	Dextrose. Lactose.	Dextrose. Lactose hydrate.	Dextrose. Maltose.	Dextrose. Maltose hydrate.
50	0.905	0.945	0.620	0.589	0.510	0.489
100	0.906	0.947	0.629	0.598	0.517	0.491
150	0.913	0.950	0.635	0.604	0.522	0.496
200	0.917	0.952	0.642	0.611	0.528	0.502
250	0.921	0.955	0.650	0.618	0.534	0.508
300	0.924	0.957	0.657	0.624	0.540	0.513
350	0.928	0.960	0.665	0.631	0.546	0.519
400	0.932	0.963	0.672	0.638	0.552	0.525
450	0.935	0.965	0.679	0.645	0.559	0.531
	0.920	0.955	0.651	0.618	0.534	0.508

These ratios were calculated from the sugar values corresponding to the several weights of copper in Table XI. The ratios for levulose and invert sugar are approximately equal to those obtained by Browne<sup>38</sup> using Allihn's method. The ratios for lactose and maltose are lower than those obtained by others.<sup>39,40</sup>

### Determination of Reduced Copper.

Three different methods were used (1) direct weighing of cuprous oxide, (2) E. C. Kendall's<sup>28</sup> modified iodide method, and (3) H. T. Beans and J. W. Stillman's<sup>24</sup> electrolytic method. For economy of space our extensive comparative tests of these three methods are omitted.

While the direct weighing of cuprous oxide is the quickest, it is liable to inaccuracy when solutions other than of pure sugars are used due to contamination of the precipitate with mineral and organic impurities. The extent of this error has been shown by Sherwood and Wiley.<sup>41</sup>

Kendall's modified iodide method is rapid but has the disadvantage of a poor end-point.

The reduced copper values given in the main sugar table No. XI and in most of the other tables in this paper were determined by the Beans and Stillman electrolytic method. This new electrolytic method is very rapid, and since the technique is at present available only in the original dissertation, it seems desirable to abstract it in brief.

**Electrolytic Method.**—The cuprous oxide is dissolved with 10 to 20 cc. of 16 *M* nitric acid, and the solution diluted to about 200 cc. with distilled water. Ten cc. of a 3% hydrogen peroxide is added. The solution is then electrolyzed at room temperature (18° to 25°) with a current of 1 ampere and an e. m. f. of from 2.5 to 3.5 volts. A weighed 50-mesh, platinum-gauze cathode and a platinum-wire spiral anode serve as electrodes. A mechanical stirrer is used so that there will be rapid agitation of the

<sup>38</sup> Browne, *op. cit.*, 1912, p. 421; *THIS JOURNAL*, 28, 436 (1906).

<sup>39</sup> Browne, *op. cit.*, p. 421.

<sup>40</sup> Sherman, "Organic Analysis," Macmillan and Co., 1918, p. 73.

<sup>41</sup> Sherwood and Wiley, *Bur. Chemistry, Bull.* 105, 120 (1907).

electrolyte. During the electrolysis a 3% solution of hydrogen peroxide is constantly dropped into the electrolyte. When the solution has become colorless, the sides of the beaker and the cover glasses are washed with distilled water, thus raising the level of the electrolyte and exposing a new surface of the platinum cathode. The process is continued until this new surface shows no deposit of copper. When the electrolysis is complete, the cathode is quickly lifted from the solution without interrupting the current and placed in a beaker containing distilled water. The electrode with its deposit of copper is washed with 95% alcohol, dried in an oven at 100° for a minute or two, then cooled in a desiccator, and weighed.

### Accuracy of Proposed New Method for Determination of Reducing Sugars.

Under the conditions for reduction, a series of experiments with dextrose and lactose was performed to study the degree of accuracy of the method.

TABLE XIII.

Reduction of Fehling Solution by Reducing Sugars.

Wt. of sugar in mg.	Reduction in mg. of copper.				
Dextrose.	(1).	(2).	(3).	(4).	(5).
20	42.2	42.0	42.6	42.3	42.3
50	102.3	102.4	102.4	102.9	102.6
100	201.2	201.2	201.0	201.2	201.1
150	295.2	...	295.1	295.4	...
200	385.1	385.6	385.0	385.4	384.8
250	472.7	...	473.2	472.6	472.7
Lactose.	(1).	(2).	(3).		
10	10.7	11.3	10.6		
50	61.2	61.3	61.6		
100	122.5	122.1	123.0		
150	184.0	184.2	184.4		
200	245.7	246.6	245.9		

From the above Table, the mean error of the mean computed from the least square equation,  $m = \pm \sqrt{\frac{\sum d^2}{n(n-1)}}$  was calculated, where,  $m$  is the mean error of the mean;  $d$  the deviation from the mean, and  $n$  the number of determinations.

The mean error of the mean for dextrose and lactose under these conditions appears to be  $\pm 0.08$  and  $\pm 0.17$  mg. of copper respectively. The percentage error is approximately  $\pm 0.12\%$ . Besides the "mean error," in the mean there may be constant errors which arise either during the preparation of the solution and weighing of samples, etc. These results show that the method is highly accurate compared with the current methods of sugar analysis, and the slight differences may be called negligible.

TABLE XIV.  
The Effect of Temperature Deviations.

Wt. of sugar in mg.	Temperature. °C.

50	102.1	102.0	102.5	102.3	103.7
100	201.5	201.9	202.2	202.7	203.4
200	385.7	385.9	386.2	386.7	387.2
Lactose.					
100	120.7	121.6	122.2	123.5	124.5
200	244.3	245.0	245.6	246.6	247.2
300	366.8	367.3	368.2	368.7	370.2

The mean error of the mean as calculated from these figures appears to be  $\pm 0.23$  and  $\pm 0.44$  mg. of copper for dextrose and lactose respectively for every degree of temperature change around  $80^\circ$ , and  $\pm 0.50$  and  $\pm 0.94$  mg. of copper for dextrose and lactose for every  $2^\circ$ . This error is approximately equal to  $\pm 0.3\%$  for  $\pm 1^\circ$  and  $\pm 0.65\%$  for  $\pm 2^\circ$  around  $80^\circ$ . The greater difference in reducing value for lactose may be ascribed to its greater susceptibility to decomposition by Fehling solution. Experiments show that the temperature can be regulated with a set of burners, and results indicate that the error introduced by fluctuations in temperature of  $\pm 1^\circ$  does not materially affect the degree of accuracy required for most purposes. For high accuracy an automatically temperature controlled bath should be used.

### Summary.

The various sources of error in current methods for using Fehling solution have been discussed.

The interrelationship of temperature,  $60^\circ$  to  $110^\circ$ , and time of heating, 10 minutes to 2 hours, to determine the best time and optimum temperature for reduction has been investigated.

Fehling reagent has been studied from the standpoint of nature and concentration of alkali, concentration of copper sulfate and Rochelle salt to find the maximum and minimum concentrations of these constituents necessary to give the greatest yield of cuprous oxide and to ensure the formation of the complex cupric tartrate ion.

Auto-reduction of Fehling solution at different times and degrees of heating has been measured, revealing those conditions under which absolutely no "blank" reduction is obtained.

Conditions affecting the physical properties of the precipitated cuprous oxide, the photosensitiveness and keeping quality of Fehling solution have been recorded.

A study of surface oxidation involving different methods of heating and receptacles of various sizes has been carried out in order to determine

the amount of copper lost due to surface oxidation and how to avoid it. The catalytic effect of the walls of the container has been demonstrated.

A procedure for the proposed method with comparison of results for the determination of the reduced copper has been described, including a discussion of the degree of accuracy of the new method.

The reducing action of sucrose on Fehling solution, alone and when mixed with different proportions of reducing sugars, has been investigated with the view of elimination of the use of empirical formulas and factors for calculation of errors involved.

The new method is designed for use in the analysis of saccharine materials containing sucrose, dextrose, levulose, invert sugar, lactose and maltose. It is not claimed that this method can be used for the accurate quantitative determination of 0.1% or less of invert sugar in approximately pure sucrose.

## VISCOSITY OF GELATIN SOLUTIONS.

BY CLARKE E. DAVIS, EARLE T. OAKES AND HAROLD H. BROWNE.

Received March 7, 1921.

Owing to the divergence of results and conclusions arrived at regarding the various physical properties of gelatin solutions an investigation of the effects of different physical and chemical treatments of such solutions has been undertaken by this laboratory.

In this paper the investigation of the viscosity of gelatin solutions is described. Detailed results of the effects on viscosity of (1) method of effecting solution, (2) aging of solution, (3) concentration of hydrogen ion, (4) concentration of gelatin, (5) hydrolysis of gelatin are given for three different types of gelatins. Finally, a method is given whereby the viscosity of a gelatin may be determined with an accuracy well within 0.5%.

Previous work has shown that viscosity is affected by the age of the solution, concentration of the gelatin, the temperature employed for effecting solution and by the character of the gelatin. With the exception of the first two factors very few, if any, results of a definite nature have been published. Much work has been done on the effects of various salts, but Loeb<sup>1</sup> has shown the fallacy of the "Hofmeister Series" and has furnished adequate chemical data in explanation of such salt effects.

<sup>1</sup> Loeb, *J. Gen. Physiol.*, [III] 1, 85 (1920).

Gelatins are of at least three kinds, depending upon the method of manufacture. No. 1 is obtained by extracting ground bones with water, leaving the mineral matter behind. No. 2 is obtained as a residue from the same source by dissolving the mineral matter in dilute acid; No. 3 is obtained by extracting hides with water, concentrating, grinding and drying. Samples of all three kinds were used in this investigation. The various grades of these different kinds depend upon the temperature and length of time required for solution. The last fractions dissolved having been subjected to the water at a higher temperature for a greater length of time furnish the weaker jells and are probably more hydrolyzed as well as more affected by any bacterial action that may have been proceeding during the manufacture. Table I will show as nearly as is possible, at the present time, the characteristics of the three gelatins investigated.

TABLE I.

Gelatin	Moisture.	Ash.	$p_H$ in 1% Sol.	Jell strength.	Bacteria per g.
1	8.93	2.39	5.5	59	22,000
2	11.25	.84	4.1	430	200
3	5.25	1.03	4.0	800	100

The jell strengths of these gelatins were determined by a more or less arbitrary procedure. A solution of 30 g. of gelatin in 180 cc. of water was heated to 60° and placed in a standard glass of 250 cc. capacity. This was cooled to 21°  $\pm$  0.1° and maintained at this temperature for 16 hours. Then the number of grams required to force a plunger a certain distance into the surface of the gelatin was determined by a method which will be described in detail in a later paper.

The  $p_H$  values of the dry gelatin were determined by applying indicators directly. This gave an accuracy of 0.2 or 0.3 in the  $p_H$  value. In determining the hydrogen-ion concentration of solutions, comparison with the color of the indicators in buffer solutions of known hydrogen-ion concentration was necessary. By employing buffer solutions and indicators as described by Clark and Lubs<sup>2</sup> an accuracy of less than 0.2 was readily attained except at a  $p_H$  of 4 to 4.5 where the solution absorbs so much of the red rays as to render color comparison with buffer solutions difficult. 1% solutions of all gelatins gave the same hydrogen-ion concentration as did the dry gelatins.

### Method of Effecting Solutions.

Preliminary determinations of the variation of viscosity of solutions of a given gelatin with change in hydrogen-ion concentration gave erratic results. From these preliminary data we were convinced however of two things. First there is a distinct effect of hydrogen-ion concentration on viscosity and second the dissolving temperature has an effect on the nature of the solution. These first results plainly showed that the alkaline solutions were more difficult to effect than the acid ones. For concordant viscosity results on solutions of the same gelatin the dissolving temperature of the alkaline solutions must be greater than of the acid solutions. Upon a more complete investigation of the effect of the temperature employed for bringing about solution it was found that all solutions brought to a temperature of 75° gave concordant viscosity results. At temperatures somewhat lower than this the results on different portions of the same so-

<sup>2</sup> Clark and Lubs, *J. Wash. Acad. Sci.*, 6, 483 (1916); *J. Biol. Chem.*, 25, 479 (1916).

lution did not agree. At higher temperatures there was a rather rapid lowering in viscosity. At the boiling temperature this decrease in viscosity was extremely rapid as will be noted in the results given in Table II and plotted in Fig. 1. These results, which are quite in accord with the previous work of Von Schroeder,<sup>3</sup> show that a very few minutes' boiling reduced the viscosity of a high grade gelatin to that of a low grade one and entirely destroyed its tendency to increase in viscosity with aging of solution. Excessive temperatures should therefore be avoided in

Fig. 1.

effecting solution. Since a temperature of 75° served to produce solutions whose viscosity could be accurately duplicated over the entire range of hydrogen-ion concentration and lower temperatures did not, this was selected as the standard. At this temperature the hydrolysis of the gelatin with its consequent lowering of viscosity was very slow except in certain cases detailed later.

From this preliminary work the following standard procedure was adopted. Ordinary distilled water ( $p_H$  value about 5.6) is made acid or basic by the addition of such quantity of 0.2 *M* hydrochloric acid or 0.2 *M* sodium hydroxide as will bring the resulting gelatin solutions to the required hydrogen-ion concentration. The gelatin is added to such

quantity of this solution as will give the required weight concentration. The age of the solution is reckoned from the time the gelatin is placed in contact with the water. As soon as the gelatin is added the flask is placed on the hot plate and brought to a temperature of 75° in 20 minutes, and stirred constantly. The solution is then filtered and placed in the thermostat at 25°  $\pm$  0.02°. When the solution registers this temperature 5 cc. is pipetted into an Ostwald viscometer and the whole immersed in the thermostat for at least 10 minutes. The solution is then drawn into the bulb of the viscometer and the run made while in the thermostat, timing the flow with a stopwatch. Three or four runs were made on each solution, using different viscometers of water equivalents of 73.8, 75.0, 78.4 and 75.8 seconds respectively. Specific gravity determinations were made by means of a pycnometer. The viscosity coefficient was calculated according to the customary formula,

$$\eta \text{ (Gelatin)} = \eta \text{ (Water)} \times \frac{(\text{Sec. gel. sol.}) \times (\text{Sp. gr. gel. sol.})}{(\text{Sec. water}) \times (\text{Sp. gr. water})}$$

$\eta$  for water being taken as 0.008937 absolute units or 0.8937 c. p. as given by Bingham.<sup>4</sup> Curiously enough no appreciable difference could be detected in the density of the solutions of the different grades of gelatin from the poorest to the best. The variation of the densities with different

<sup>4</sup> Bingham. Bur. Standards, *Bull.* 298, 74 (1917).

values of the concentration of the hydrogen ion was negligible in its effect on viscosity results.

In all our computations the density of the 1% gelatin solutions at 25° was taken as 1.0000. Actual variations were encountered from 1.00008 to 0.99988. The densities of gelatin solutions will be discussed in detail in a later paper.

The instruments were cleaned after each run by sucking through hot tap water and then distilled water by means of the filter pump. They were then placed in an air-oven and heated and air drawn through them while they were still warm. It is extremely important that the viscometer be absolutely dry when the gelatin solution is drawn into the side tube, as otherwise bubbles will be formed and correct results cannot be obtained. The  $p_H$  values between 2 and 9 were determined colorimetrically with the indicators and buffers of Clark and Lubs.<sup>3</sup> Other values were determined with the hydrogen electrode, using the condenser method described by Beans and Oakes.<sup>5</sup> The hydrogen electrode also served to check colorimetric determinations.

This procedure was found to give such satisfactory results that it was followed for all the viscosity determinations. It was found that under identical conditions the viscosity of solutions of any gelatin could be duplicated at will within the accuracy of the stopwatch. This gave an accuracy in the absolute viscosity values of  $\pm 5$  in the fifth decimal place, or in the third decimal place where viscosity is given in c. p. or an error of about  $\pm 0.5\%$  at the most.

### Effect of Age of Solution on Viscosity.

Attention has been directed to the fact that gelatin solutions increase in viscosity for a period of time, reach a maximum and then diminish in viscosity. This phenomenon has been investigated for all three kinds of gelatin. It has been found that the maximum viscosity is attained in about 24 hours. Solutions of the higher grade gelatins may then still continue to increase slowly in viscosity. The low grade gelatins show a fairly rapid decrease especially where the  $p_H$  value of the solution is between about 5 and 8. It was noted that in every case where the viscosity began to decrease the solution smelled putrid; it was the gelatin of the highest bacterial content that decreased most rapidly; the decrease was accelerated by conditions favoring bacterial growth.

Table III shows the effect of age on the lowest grade of gelatin which also contains the greatest number of bacteria per gram. In Table IV will be found data covering the effect of age on solutions of the highest grade gelatin over periods of 1 and 2 hours.

<sup>5</sup> Beans and Oakes, *THIS JOURNAL*, 42, 2116 (1920).

90	48	1.075

The viscosities of solutions of various concentrations of all three gelatins were investigated over a range of  $p_H$  value 1.5 to 12.9. In order to show in detail the method of procedure the complete results on 1% solutions of Gelatin No. 3 are given in Table IV. The last column gives the increases in viscosity during the second hour multiplied by 100 to avoid the use of small fractions. Similarly 0.5% and 0.25% solutions of this same gelatin were investigated.

In Fig. 2 the viscosity values for all three concentrations are plotted for  $p_H$  4.0, while in Fig. 3 corresponding values for  $p_H$  6.5 are plotted. Reference to these curves (Figs. 2 and 3) shows that the rate of increase

Fig. 2.

in viscosity with aging of solution differs at different  $p_H$  values. In Fig. 4 the viscosity-age of solution results are plotted for several different  $p_H$  values for 1% solutions of No. 3 gelatin. From this figure it is seen that the slopes of the curves increase with concentration of hydroxyl ion until a maximum is reached when the slope drops rapidly to a new low level. In order to represent this more clearly the values of  $10^3 \frac{\Delta \eta}{\Delta t}$  for the second hour of age of solution have been plotted in Fig. 5. In this figure the corresponding values of No. 2 gelatin are also given, No. 1 gelatin gave such small values as could not be plotted on the same scale with No. 2 and No. 3. From Fig. 5 it is seen that the viscosity is increasing most rapidly around a  $p_H$  value of 8. At a concentration of hydroxyl ion greater than  $p_H = 9$  there may even be a decrease in viscosity. This effect is taken up later under hydrolysis of gelatin.

Fig. 3.

We may then conclude from the results described above that a solution

Fig. 4.

of gelatin of  $p_H$  value less than 9 increases in viscosity with increase in age, reaching a maximum in about 24 hours. A decrease in viscosity after the maximum is reached indicates bacterial decomposition. The increase in viscosity with age varies directly with the hydroxyl-ion concentration until a maximum is reached at  $p_H$  8 to 8.5. At greater hydroxyl-ion concentration the in-

crease diminishes rapidly and actually becomes a minus quantity at  $p_H$  values somewhat greater than 9. In the case of pure, strong, slightly hydrolyzed gelatin the increase is very rapid. Very low grade gelatins show but slight increase in viscosity with age of solution.

Fig. 5.

#### Effect of Concentration of Gelatin on Viscosity.

In Figs. 2 and 3 the viscosity-concentration values of No. 3 gelatin are plotted for  $p_H$  4.0 and 6.5 respectively. In Fig. 8 the corresponding values for No. 1 gelatin are plotted for  $p_H$  3.6 and 5.0. In the case of No. 1 the concentrations were carried to 3%. With No. 3, solutions of greater concentration than 1% jellied too rapidly to give reliable results. For low concentrations of fairly acid solutions the viscosity is approximately a linear function of the concentration.

On the alkaline side of the iso-electric point ( $p_H$  4.7) the viscosity increases so rapidly with increasing concentration that it does not even approximate a linear function of the concentration. It is quite evident from the above that neither Einstein's<sup>6</sup> formula for the viscosity of a colloid solution nor any modification so far proposed for it can be used to compute the viscosity of gelatin solutions at different concentrations. Viscosity-concentration formulas for gelatin solutions would require an entirely different set of constants for each gelatin, each value of the hydrogen-ion concentration, each age of solution, and in addition the method of effecting solution would have to be defined.

#### Effect of Concentration of Hydrogen Ion.

Since at a temperature of 25° gelatin solutions increase in viscosity with age it is obvious that viscosity values are worthless unless the age of solution is stated. Accordingly in all our work a number of determinations were made on each solution. From these values a graph was constructed from which the viscosity of the solution at any particular age

<sup>6</sup> Einstein, *Ann. physik.*, 19, 289 (1906).

could be determined. Selecting the values for an age of solution of 85 minutes the viscosity- $p_H$  values for 0.25 to 0.5% and 1% solution of No. 3 gelatin were plotted in Fig. 6. In Fig. 7 the corresponding values for 1% solutions of No. 1 and No. 2 are plotted with the values for 0.25% solutions of No. 3 repeated for comparison. 1% solutions of No. 3 gelatin are increasing in viscosity so rapidly that the gelation factor has entirely masked the effect of hydrogen-ion concentration. The other curves show a distinct maximum at  $p_H$  3.0 to 3.5 when the viscosity is taken at an age of solution of 85 minutes and  $25^\circ$ . On the alkaline side of the iso-electric point the corresponding viscosities plot a straight line until such a concentration of hydroxyl ion is reached as will catalyze the hydrolysis of the gelatin as described later. On the acid side the curves are essentially the same as described by Loeb.<sup>1</sup> On the alkaline side the type of curve is quite different since Loeb records a maximum at  $p_H$  11 approximately. Since Loeb<sup>7</sup> used an entirely different procedure undoubtedly a difference in the ages of the solutions accounts for the difference in the types of the curves. The maximum in the curve at  $p_H$  3 to 3.5 is unaccounted for except on the assumption of the formation of a compound at this point, data included in a paper in the course of preparation support this view.

### Effect of Hydrolysis on Viscosity.

The effect of hydrolysis of the gelatin resulting from boiling the solution has been discussed. The abnormal drop in viscosity recorded in Figs. 6 and 7 at  $p_H$  values greater than 9 suggests that we are encountering an

Fig. 6.

<sup>7</sup>This work was done in the summer of 1920, before Loeb's results were published in September (1920).

effect other than that of the alkali combining with the gelatin to form a metal gelatinate. It appeared that the hydroxyl ion at this concentration was catalyzing the hydrolysis of the gelatin to such an extent as to lower the viscosity to the extent indicated in Fig. 7, the actual values being 1.251 at  $p_H$  values 6.4, 7.4, 9, and 1.047 at  $p_H$  12.9.

Fig. 7.

In order to test this point 1% solutions of No. 2 gelatin were made up in duplicate. Solution B1 was made up exactly as described heretofore. Two g. of gelatin was dissolved in 200 cc. of 0.2 M sodium hydroxide

Fig. 8.

solution, heated for 20 minutes, when a temperature of 75° was reached, allowed to cool, filtered and placed in the thermostat. At the same time Solution B2 was prepared as follows. Two g. of the gelatin was added

to 190 cc. of water and the solution accomplished exactly as in the case of Sample B1, the two solutions being carried along together. After B2 was removed from the hot plate and allowed to cool 10 cc. of a solution containing 1.6 g. of sodium hydroxide was added. The  $p_H$  value of these two solutions, B1 and B2 was 12.9. Viscosity of these solutions was found to be as follows.

Age of solution.		C. p. B1 absolute viscosity.	C. p. B2 absolute viscosity.
Hours.	Min.		
1	25	1.009	1.273
5	30	0.987	1.100
22		0.979	1.019
27		0.976	1.007
49		...	0.996

In exactly the same manner the effect of acids on the hydrolysis of gelatin solutions was determined. Solutions A1 and A2 were made up at a  $p_H$  1.4. In the case of A1, 2 g. of gelatin was dissolved in 160 cc. of water to which 40 cc. of 0.2 *M* hydrochloric acid had been added. A2 solution did not have the acid added until after the gelatin had been dissolved and the solution cooled. On these two solutions the following results were obtained.

Age of solution.		C. p. A1 absolute viscosity. $p_H$ 1.4.	C. p. A2 absolute viscosity. $p_H$ 1.4.
Hours	Min.		
1	40	1.379	1.424
22	"	1.449	1.515
28		1.447	1.501

These values indicate that hydrogen ions and hydroxyl ions catalyze the hydrolysis of gelatin. Hydroxyl ion catalyzes this reaction to a very great extent at  $p_H$  values greater than 9. The effect of hydrogen ion up to  $p_H$  1.4 is slight compared to the hydroxyl-ion effect. In order to avoid the hydrolysis effect the acid and the alkali should not be added to the solution until after it has been cooled. The procedure would then be to dissolve the gelatin in pure water and after the solution has cooled add the required amount of alkali or acid to bring the solution of gelatin to the required hydrogen-ion concentration making the total volume such as will give the desired gelatin concentration. This would only be necessary where the hydrogen-ion concentration of the resulting solution was outside the range of  $p_H$  2.5 to 8.

### Summary.

1. Effects on the viscosity of gelatin of (a) method of effecting solution, (b) aging of solution, (c) hydrogen-ion concentration, (d) concentration of gelatin, and (e) hydrolysis of gelatin, have been described for three different kinds of gelatin.

2. A method of determining viscosity of gelatin solutions with a maximum error of 0.5% has been described.

3. Gelatin solutions increase in viscosity with age at different rates depending upon concentration of gelatin, hydrogen-ion concentration, and kind of gelatin.

4. For any given gelatin solution a maximum viscosity is attained at an age of solution of about 24 hours. A decrease in viscosity after the maximum is reached indicates bacterial decomposition.

5. Gelatin solutions show a maximum viscosity at a  $p_H$  3.0 to 3.5 at 25°.

6. The viscosity of gelatin solutions is not a simple function of concentration of gelatin.

7. Both hydrogen and hydroxyl ions catalyze the hydrolysis of gelatin solutions, the latter more rapidly than the former.

8. Excessive temperatures catalyze the hydrolysis of gelatin. Boiling gelatin solutions hydrolyzes them very rapidly.

## THE COMPRESSIBILITY OF BENZENE, LIQUID AND SOLID.

BY THEODORE W. RICHARDS, EDWARD P. BARTLETT AND JAMES H. HODGES.

Received March 11, 1921.

Very few substances have had their compressibilities determined in both the liquid and the solid state. The comparison of the two different values is of considerable interest in relation to a study of the mechanism of the change of state in any given substance. Accordingly the present paper recounts such a comparison in the case of benzene, for which adequate data were lacking as regards the solid. The results were incidental to other researches, but seem to deserve separate publication.

Of liquid benzene, a careful determination, made in a glass piezometer, has already been described.<sup>1</sup> The object of repeating the determination was primarily to show whether or not the earlier apparatus, which had been used with a variety of substances, was adequate, by comparing a typical result with that yielded by a larger more complete piezometer free from the hysteresis to which glass is subject.

The piezometer used in the present research was the steel instrument already described in full in another previous paper.<sup>2</sup> In the case of liquid benzene, a weighed amount of about 30 cc. of this substance was placed in an inverted steel test-tube immersed under mercury (which filled the piezometer). The steel test-tube diminished the unnecessarily large volume

<sup>1</sup> T. W. Richards and J. W. Shipley, *THIS JOURNAL*, 38, 989 (1916).

<sup>2</sup> T. W. Richards and E. P. Bartlett, *ibid.*, 37, 470 (1915).

of the apparatus and kept the benzene from being entrapped in the washer and screw-thread. During the operation of filling, the utmost care was exercised against the introduction of air. From Amagat's measurement of the compressibility of air<sup>3</sup> 1 cc. at 0° and 1 atmosphere changes in volume by 0.007 cc. between 100 and 500 atmospheres. Since the present method is sensitive to perhaps within 0.0001 cc., the presence of even 0.01 cc. of air should be avoided. Accordingly, after having been thoroughly cleaned and dried, the piezometer was filled with mercury through a funnel tube with a capillary outlet reaching to its bottom. The mercury thus rose quietly in the steel tube, without entrapping air. The iron washer was slipped edgewise under the mercury, and put in position with two glass rods. The piezometer was then ready to receive the tube containing the hydrocarbon. The benzene having been inserted, the cap-piece of the piezometer with the attached capsule, was carefully put in position and held firmly until the nut was screwed into place, when, with a special vise, the nut was tightened as much as possible, using a long lever to complete the closure.

It was by no means so easy to arrange the solid benzene for compression. In the first place, the steel piezometer was prepared as before in every respect for the reception of the tube containing the benzene, since its introduction was a process demanding great celerity, as will be seen.

The hydrocarbon was enclosed in a glass tube of 17.82 cc. capacity, drawn down to a capillary opening. This tube had been filled by placing it in a large test-tube containing the liquid, and by alternately exhausting and admitting pressure. Unfortunately benzene dissolves a considerable amount of air,<sup>4</sup> which separates when the liquid is frozen. Accordingly, when the tube was completely full of benzene, the whole apparatus was immersed in ice water, still keeping it at low pressure. As the liquid froze, the dissolved air was set free. Because, however, the crystals entangled a few bubbles, the benzene was melted and frozen again several times successively, until no further air appeared on freezing. The apparatus was finally warmed to about 23° and the tube removed, wiped, and weighed as quickly as possible on a balance already holding the known approximate weights. Slight warming brought the benzene exactly to the orifice, when the tube was quickly inverted and immediately inserted in the waiting piezometer. The only surface exposed was that in the capillary about a millimeter in diameter, so that evaporation, or solution of air, must have been negligible in the very brief time concerned. The remainder of the closing of the piezometer was conducted just as usual, and so were the details of the application of pressure.

<sup>3</sup> Amagat, *Compt. rend.*, 111, 871 (1890), and 116, 946 (1893).

<sup>4</sup> T. W. Richards, E. K. Carver, and W. C. Schumb, *THIS JOURNAL*, 41, 2019 (1919). Reference will be found in this paper to earlier work of Just, Garelli and Falciola, etc.

The piezometer was suspended in the thermostat for several minutes, and the meniscus set at a height estimated to break contact at a pressure slightly below 100 megabars. The space above the meniscus was filled with water, the platinum point screwed on, cotton placed in the openings at the top, and the piezometer carefully lowered into the pressure cylinder, which was then packed in ice. The further operations were precisely like those which have been so often described before.

Apparently, the density of solid benzene (which is needed for calculating the results) has never been determined. Various values at  $0^\circ$  are given in tables, but if these were directly determined, the measurements must have been made on the under-cooled liquid. On account of the great tendency of the liquid to dissolve air, the measurement of the specific gravity of solid benzene is not very easy. A rough determination made in the 17.82-cc. tube showed that its density is slightly over 1.000. This is confirmed by the very careful determination of the change in volume upon melting of benzene (thoroughly free from air) of Julius Meyer,<sup>5</sup> who found that one gram of benzene increases 0.1333 cc. in volume on melting. If the density of liquid benzene at its melting point is 0.8941, the density of the solid would then be 1.0151. This value (which probably differs only very slightly from the density at  $0^\circ$ ) was used in the following calculation.

Both the benzene and toluene had been very carefully purified. The benzene had been prepared by Dr. J. W. Shipley,<sup>6</sup> and the toluene by Dr. F. Barry.<sup>7</sup>

The compressibility determinations follow. The first three columns give three successive pressure measurements,  $p_0$ ,  $p_1$ ,  $p_2$ ; the next two, the weights of mercury added ( $w$  and  $w_2$ ) to obtain  $p_1$  and  $p_2$ ; the last two columns record the values for the weights calculated for two successive pressure ranges of exactly 200.00 megabars, and the calculation was made

by determining exactly the  $dv/dp$  values at about 100, 300, and 500 megabars in each case, in special trials, but could have been taken from a carefully plotted curve.

Calculated by the equations given in a previous paper<sup>8</sup> these data give the following values for the compressibility of benzene.

#### RESULTS. COMPRESSIBILITY OF LIQUID AND SOLID BENZENE.

	Range 100-300.	Compressibility $\times 10^4$ . Range 300-500.	Range 100-500.
Liquid Benzene at 20.00°.....	77.68	66.46	72.07
Solid Benzene at 0°.....	31.69	29.30	30.49

Evidently the compressibility of the solid is far less than that of the liquid, as is also its decrease with increasing pressure. Of course the comparison should properly be made with each phase at the same temperature; but the compressibility of the liquid cannot be determined at 0°. Some clue as to the effect of changing temperature may be found from the parallel behavior of liquid toluene. In the same apparatus as that used for solid benzene, one of us (E. P. B.) found that with 15.459 g. of toluene  $d_4^{20}$  0.8845) the averaged values of ( $w_1$ ) cor. and ( $w_2$ ) cor. were respectively 3.4397 g. and 3.0370 g. These figures lead to the following values of the compressibility of toluene, which are compared with those previously found <sup>1,9</sup> at 20°.

#### RESULTS. COMPRESSIBILITY OF TOLUENE AT 0° AND 20°.

	Range 100-300.	Compressibility $\times 10^4$ . 300-500.	100-500.
Toluene at 0°.....	65.98	57.61	61.78
Toluene at 20.00°.....	74.07	63.93	69.00

The change of 20° affects the compressibility by about 10 or 11%. Probably the compressibility of benzene would show a somewhat larger

<sup>8</sup> Richards, Stull, Mathews and Speyers, THIS JOURNAL, 34, 980 (1912), on last half of the page.

<sup>9</sup> This value agrees exactly with that found in an earlier research, (*ibid.*, 34, 988, (1912)).

temperature effect, so that its liquid compressibility at  $0^\circ$  would be not far from 0.000063, (over the range 100 to 500 megabars) whereas that of the solid is only 0.0000305 — less than half the former.

The comparison of these results with those of other experimenters is interesting. In the first place, the result 72.07 for benzene at  $20^\circ$  confirms satisfactorily the most recent previous result 72.09 obtained with a quite different form of glass apparatus.<sup>1,10</sup> This indicates consistency, and inspires confidence in both techniques. Evidently the needful precautions against complication by the hysteresis of glass had been properly observed.

Apparently the only earlier determination of the compressibility of solid benzene was that of Harry Essex.<sup>11</sup> He gives as the relative volumes of the substance at  $0^\circ$ , 0.87045, 0.84561 and 0.83277 at 1, 500 and 1000 kg/cm<sup>2</sup>, respectively. The existence of these unusual results, which give an average compressibility  $59. \times 10^{-6}$  over the first range, and  $29.4 \times 10^{-6}$  over the second range, had been among the reasons for the present study. In the light of our data, it seems possible that the benzene used by Essex had not been freed from air, of which he makes no mention. The presence of only about 1.5% by volume of air would account for the wide variation shown by his own figures, as well as the discrepancy between his and ours. In that case his values for the higher pressures are doubtless much more nearly correct than those for the lower pressures.

We are indebted to the Carnegie Institution of Washington for some of the apparatus used in this research.

### Summary.

This brief paper records for the first time an accurate determination of the compressibility of solid benzene at  $0^\circ$ , namely  $(\Delta V/\Delta PV_0)_T = 0.0000305$  over the range 100 to 500 megabars.

Incidentally, the compressibility of liquid toluene at  $0^\circ$  over the same range was found to be 0.0000618.

A new determination of the compressibility of liquid benzene at  $20^\circ$  confirmed satisfactorily the previous determination, giving the value 0.00007207 for the same range.

The compressibility of solid benzene is shown to be less than half that of liquid benzene at the same temperature. Thus another case, supporting the majority of those investigated, is found in which the solid shows much smaller compressibility than the liquid.<sup>12</sup> Interpretation of the result will be postponed until more cases of this kind have been studied.

## THE EXISTENCE OF TETRAHYDRATED SODIUM SULFATE IN MIX-CRYSTALS WITH SODIUM CHROMATE.

By THEODORE W. RICHARDS AND W. BUELL MELDRUM.

Received March 11, 1921.

Dekahydrated sodium chromate and sodium sulfate form mix-crystals in almost all, if not all, proportions. The present note proves that the tetrahydrate of sodium chromate also is capable of isomorphously dissolving sodium sulfate, in spite of the fact that  $\text{Na}_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$  does not exist by itself.

The induced crystallization of one salt by a second, in the otherwise unattainable form of hydration of the second, is well known in several other instances: for example, the crystallization of cupric sulfate heptahydrate,  $\text{CuSO}_4 \cdot 7\text{H}_2\text{O}$ , with ferrous sulfate heptahydrate.<sup>1</sup> Nevertheless, cases of this kind are not so numerous as to make the addition of another to their number superfluous: hence the publication of the present brief paper, which records a side-issue of a comprehensive investigation of the sulfate-chromate equilibrium.

That mix-crystallization occurs with sodium chromate tetrahydrate might be inferred from the fact that sodium sulfate is eliminated only very slowly during recrystallization of the tetrahydrate of sodium chromate.<sup>2</sup>

This conclusion was strongly supported by preliminary analysis of crystals of tetrahydrated sodium chromate obtained from warm solutions of sodium chromate containing considerable sodium sulfate, which had been washed four times with a pure saturated solution of sodium chromate while the crystals were stirred with the washing liquid. After crushing and air-drying to the first visible trace of efflorescence, 0.8712 g. of these crystals lost 0.2695 g. (or 30.93%) of water on complete dehydration: and 7.06% of sodium sulfate was found in the residue. The theoretical water content for this mixture if both salts were present in the form of tetrahydrate would be 30.96%, or almost exactly that found.

Evidence that the sulfate thus found was not due to remaining mother liquor was afforded by the fact that the second and fourth wash-solutions contained approximately identical percentages of sulfate. It was necessary to make sure, however, that separate crystals of partly dried ordinary Glauber's salts were not present. Therefore in subsequent trials not only the crystallization but also the filtering, washing with pure saturated

<sup>1</sup> Marignac, *Ann. Mines*, 9, 1 (1856); also Lecoq de Boisbaudran, *Ann. chim. phys.*, 18, 246 (1860). See also Stortenbeker, *Z. physik. Chem.*, 16, 250 (1895); and Retgers, *ibid.*, 16, 580 (1895), and 15, 571 (1894).

<sup>2</sup> T. W. Richards and G. L. Kelley, *Proc. Am. Acad.*, 47, 173 (1911).

chromate solution and drying were conducted about 32.4°. The final drying of the crystals was accomplished by allowing them to stand over dil. sulfuric acid of such concentration that its vapor pressure was slightly less than that of the solution of sodium chromate saturated at the same temperature. Six separate crops of crystals were prepared from different solutions and treated in this way before analysis. Sample 2 consisted of short, fine powdery crystals; Samples 3 and 4, of fine needles; Samples 5 and 6, after drying to constant weight, were afterwards crushed and again placed in the desiccator. Sample 7 was exposed to an atmosphere dry enough to dehydrate crystals containing 10 molecules of water. Samples 8 and 9 consisted of very large, clear crystals crystallized at 23° and picked out carefully by hand.

TABLE I.  
Analysis of Tetrahydrated Mix-crystals.

Sample.	Weight crystallized salt. G.	Weight water. G.	Na <sub>2</sub> SO <sub>4</sub> in anhydrous residue. %.	Per cent. of water. Observed. %.	Calc. for 4H <sub>2</sub> O for both salts. %.
2	1.2785	0.3985	5.08	31.2	30.9
3	2.3503	0.7335	3.25	31.2	30.9
4	2.0832	0.6635	2.97	31.8	30.8
5	0.8716	0.2703	3.25	31.0	30.9
6	1.5546	0.4821	2.97	31.0	30.8
7	1.4003	0.4323	3.07	30.9	30.9
8	1.5940	0.5010	8.58	31.4	31.0
9	1.7098	0.5296	4.39	31.0	30.9

In every case except No. 4 (in which the fine needles had apparently not been adequately dried), the amount of water was within the usual limit of error in such cases. If all the sulfate in Expt. 8 had been dekahydrated, the percentage of water found would have been 35.9, instead of 31.4. There can thus be no question that sodium sulfate crystallizes with sodium chromate in the form of tetrahydrate, Na<sub>2</sub>SO<sub>4</sub>·4H<sub>2</sub>O. The effect of the dissolved sulfate on the crystal angles would be a matter of interest, but time was lacking for its study.

The distribution of sodium sulfate between the crystals and their mother liquor was approximately determined by analysis of mother liquors from new tetrahydrate crystals as follows.

Na <sub>2</sub> SO <sub>4</sub> in dried crystals. %.	Na <sub>2</sub> SO <sub>4</sub> in dried salt from liquid. %.	Temperature of formation. °C.
4.39	10.38	23
2.97	8.00	33

These make no pretension to great accuracy, but show roughly that the sulfate under these conditions is distributed between the crystals and the salts in solution in the ratio 1:2.5, approximately. This is, of course,

a far smaller proportion of sulfate in the crystals than in the case of decahydrate, but is quite enough to account for the difficulty in eliminating sodium sulfate from chromate by crystallization as tetrahydrate.

When sodium sulfate was in large excess, in repeated trials, no crystallization could be induced by inoculating the saturated mixture with the crystal of the tetrahydrate above the transition temperature of sodium sulfate, and below this temperature only crystals of the decahydrate could be made to form. Thus under these conditions the tetrahydrate is so much more soluble than the phases containing more sodium sulfate as to be incapable even of meta-stable existence.

### Summary.

In brief, this paper shows that crystals of  $\text{Na}_2\text{CrO}_4 \cdot 4\text{H}_2\text{O}$  dissolve sodium sulfate as  $\text{Na}_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$  (a form otherwise unknown) to the extent of somewhat less than half the quantity corresponding to the same weight of sodium chromate in the supernatant solution.

## THE SOLUBILITIES OF ACIDS IN AQUEOUS SOLUTIONS OF OTHER ACIDS.

By JAMES KENDALL AND JAMES C. ANDREWS.

Received March 24, 1921.

The factors controlling addition-compound formation in systems of the type  $\text{HX}:\text{HY}$  have been investigated in an earlier article.<sup>1</sup> It has been established that a weak acid in the presence of a strong acid behaves as a base, the stability of the resultant "salt" depending upon the difference in acidic strengths. Precisely the same factors are operative in determining the hydration of an acid in aqueous solution, the extent of compound formation between acid and water increasing uniformly with the strength of the acid.<sup>2</sup> When we come to consider the three-component system  $\text{HX}:\text{HY}:\text{H}_2\text{O}$ , the equilibria involved are naturally more complicated. By investigation of the solubility curve for one acid  $\text{HX}$  in solutions containing increasing concentrations of the second acid  $\text{HY}$ , however, we can obtain valuable evidence with regard to the existence and stability of compounds between the two acids in aqueous solution. The problem resembles in certain respects one already taken up in a previous paper<sup>3</sup>—the effect of other chlorides upon the solubility of silver chloride in water—but is obviously considerably more intricate in view of the wide variations possible in the solubilities and in the ionization constants of the two acids selected.

<sup>1</sup> Kendall, *THIS JOURNAL*, 36, 1722 (1914).

<sup>2</sup> Kendall, Booge and Andrews, *ibid.*, 39, 2303 (1917).

<sup>3</sup> Kendall, Davidson and Adler, *ibid.*, 43, 1496 (1921).

It must be admitted that final conclusions upon systems of this nature cannot be arrived at until considerable advances in our general theory of solutions have been made (at present, the nature of the equilibria in the simple system  $HX:H_2O$  is still debatable), but by the comparison and correlation of typical cases we may hope to gain some insight into the factors concerned which will prove of assistance in the subsequent development of this general theory.

The case where  $HX$  is a typical weak acid and  $HY$  a typical strong acid may be briefly analyzed as an illustration. If no compound formation occurs in aqueous solution, the addition of  $HY$  to a saturated solution of  $HX$  in water theoretically necessitates a sharp dip in the solubility curve of  $HX$  until the "constant undissociated value" is reached,<sup>4</sup> since the ionization of the weak acid will be reduced practically to zero in the presence of the strong acid. Further addition of  $HY$  will have little effect.<sup>5</sup> If compound formation does occur, however, an opposing factor upon the solubility curve is immediately introduced. Addition of  $HY$  now involves the removal of  $HX$  molecules as such from the solution to form molecules of the complex, consequently more solid  $HX$  must dissolve to re-establish equilibrium. The more stable the compound, the more marked will be this effect. In an extreme case it may even wipe out the sharp initial "ionic" decrease in solubility, increasing values being recorded from the very start. If the dissociation of the compound into its components in the solution is extensive,<sup>6</sup> on the other hand, the increase in the solubility may not appear until very high concentrations of  $HY$  are reached. In such a system the solubility curve will exhibit a characteristic minimum.

Other types of solubility curve will result when two acids of similar character are chosen, or when the order of acidic strengths is reversed. Assuming that the generalizations derived from the study of two-component systems are still valid, we may predict the following behavior for the various possible combinations.

(A) $HX$ weak; $HY$ strong	Extensive compound formation	Curve with a minimum
(B) $HX$ weak; $HY$ weak	Little compound formation	Curve variable; generally rising
(C) $HX$ strong; $HY$ strong	Extensive hydration; little compound formation	Curve steadily falling
(D) $HX$ strong; $HY$ weak	Extensive compound formation	Curve generally rising

<sup>4</sup> Nernst, *Z. physik. Chem.*, 4, 372 (1889); Kendall, *Proc. Roy. Soc.*, 85A, 200 (1911). See however Stieglitz, *THIS JOURNAL*, 30, 946 (1908).

<sup>5</sup> The actual course of the curve will depend primarily upon the method employed for expressing concentrations, a point which is discussed in the text later. In general, removal of water as solvent by hydration of the strong acid  $HY$  will result in a gradual further decrease in the solubility of  $HX$ .

<sup>6</sup> In view of the large excess of water present, this may in practically all systems be presumed to be the case.

In systems of the Type B the predominant factor in determining the final course of the solubility curve will be changes in internal pressure, the effect of which has been discussed in detail by Hildebrand and his collaborators in a recent series of articles.<sup>7</sup> If the difference in the internal pressures of HX and HY in the liquid state is smaller than the difference in the internal pressures of HX and H<sub>2</sub>O we may expect the solubility to increase, if it is larger we may predict a decrease. Since most weak acids are organic and closely similar in character, a rising solubility value will be more frequently encountered.<sup>8</sup>

In systems of Type C, where both acids are highly polar, the chief factors will be repression of ionization and removal of solvent water by hydration of the added acid; hence in general a steadily decreasing solubility of the original acid will result. Changes in the degree of hydration as the water concentration diminishes may, however, involve changes in the nature of the stable phase and consequently induce sharp breaks in the curve.

In systems of Type D, finally, the formation of addition compounds will (as in Type A) bring about a continuous increase in solubility after the initial "ionic" effect in the opposite direction is overcome. This initial effect, however, will here be much smaller (often indeed scarcely noticeable), since the weak acid HX will not be appreciably ionized in the presence of excess of the strong acid HY. A generally rising curve may therefore be expected.

The nature of the accordance of the available experimental data with these several predictions will be taken up in a later section, after the results obtained for the systems investigated in this research have been described.<sup>9</sup>

### Experimental.

The solubility curves here examined are : (1) hydrogen sulfide in hydrochloric acid solution; (2) boric acid in hydrochloric acid and nitric acid solutions; (3) benzoic acid in hydrochloric acid and nitric acid solutions; (4) salicylic acid in hydrochloric acid and nitric acid solutions. A series of weak acids with extremely divergent properties was intentionally

<sup>7</sup> See in particular, Hildebrand, *THIS JOURNAL*, 38, 1452 (1916).

<sup>8</sup> Compare Kendall, *Proc. Roy. Soc.*, 85A, 218 (1911).

<sup>9</sup> The experimental part of this paper was completed in 1917. Owing to the absence of one of the authors on naval duty and to the pressure of other work, however, its publication has been delayed. In the interim an important investigation by Knox and Richards (*J. Chem. Soc.*, 115, 508 (1919)) has appeared, in which solubility curves for no fewer than 48 different systems of the various types discussed above are examined. The conclusions of Knox and Richards are in substantial agreement with those here expressed, and their results have been drawn upon freely in illustrating the argument in the later sections of this article.

selected, in the expectation that the comparison of the results obtained would show (a) whether weak acids of widely different acidic strengths<sup>10</sup> give curves of the same type with the same strong acids, (b) whether inorganic and organic acids behave similarly, and (c) whether a gas gives the same type of curve as a solid. In order to obtain additional information with regard to the equilibria existent in mixed acid solutions, conductivity determinations were also carried out on certain of the above systems.

After considerable hesitation as to the best method of expressing concentrations, it was decided to employ volume units (gram molecules solute per liter solution) throughout. The comparison of the results here obtained with those of previous investigators is thereby greatly facilitated.<sup>11</sup> It is recognized that the representation of all compositions in terms of mol fractions is theoretically preferable,<sup>12</sup> but until we know more about the nature of the molecular types present in the solutions here examined the evaluation of their respective mol fractions is not feasible. A possible alternative procedure is to use weight concentrations, *i. e.*, to compare solubilities in a fixed weight of water. This has the disadvantage of neglecting the added acid entirely, and since this frequently exerts a greater solubility effect than water itself, values obtained on this basis for high concentrations of added acid would often be absurdly large. The use of the volume units here adopted, it must be noted, is more apt to lead to errors in the opposite direction, owing to the fact that the molecular volumes of the added acids are, in general, considerably higher than that of water.<sup>13</sup> This is a factor which must be borne in mind throughout in making comparisons, although its exact magnitude for any particular case cannot at present be calculated. It will be partially counterbalanced in all cases by the progressive disassociation of water as the concentration of added acid is increased.

<sup>10</sup> The respective ionization constants in water are:  $\text{H}_2\text{S}$ ,  $k_{18}^\circ = 5.7 \times 10^{-8}$ ;  $\text{H}_3\text{BO}_3$ ,  $k_{25}^\circ = 6.6 \times 10^{-10}$ ;  $\text{C}_6\text{H}_5\text{COOH}$ ,  $k_{25}^\circ = 6.6 \times 10^{-5}$ ;  $\text{C}_6\text{H}_4\text{OH.COOH}$ ,  $k_{25}^\circ = 1.06 \times 10^{-8}$  (Landolt-Börnstein, "Tabellen," 1912, p. 1182, *et seq.*). Boric acid was specifically chosen because of the availability of previous conductivity data for comparison with the results here obtained (see the discussion in a later section); benzoic and salicylic acids, similarly, because of previous solubility determinations.

<sup>11</sup> Density data will be added in a subsequent article, in which the evidence afforded by solution volume changes upon hydration and compound formation will be discussed (compare Bousfield, *J. Chem. Soc.*, 107, 1405 (1915)).

<sup>12</sup> See Kendall, Davidson and Adler, *THIS JOURNAL*, 43, 1481 (1921).

<sup>13</sup> If both water and HY were quite indifferent substances with respect to HX the *mol fraction* of HX in the saturated solution would remain constant as HY replaced  $\text{H}_2\text{O}$ . Hence, if the *average molecular volume* of the solvent increases as HY is added, the *volume concentration* of HX will diminish. Hydration of HY, which will increase the *average molecular volume* of the solvent still further, involves a more rapid diminution, in the volume concentration of HX.

The System  $\text{H}_2\text{S} : \text{HCl} : \text{H}_2\text{O}$ .

A steady current of hydrogen sulfide was obtained by running ammonium sulfide solution into conc. hydrochloric acid.<sup>14</sup> The gas first passed through wash-bottles containing dil. sulfuric acid (to remove ammonia)<sup>15</sup> and concentrated sodium sulfide solution (to remove hydrochloric acid and possible traces of carbon dioxide).<sup>16</sup> It was then bubbled over a long column of aqueous hydrogen chloride solution, of the same concentration and at the same temperature as that in which its solubility was being determined,<sup>17</sup> and thence it was finally passed, by means of a capillary tube, through a standardized solution of hydrochloric acid in an absorption buret, immersed in a Freas thermostat at  $25 \pm 0.01^\circ$ . The lower portion of this buret consisted of a 50-cc. bulb above and below which the tube was calibrated. When equilibrium was established,<sup>18</sup> the buret was disconnected, a known volume of the solution was run out into a measured excess of standardized iodine solution, and the remaining free iodine titrated back by means of sodium thiosulfate.

The results given below express, first of all, the usual absorption coefficient (*i. e.*, the number of volumes of hydrogen sulfide, reduced to  $0^\circ$  and 760 mm., taken up by one volume of the solution under a pressure of hydrogen sulfide<sup>19</sup> of 760 mm.) and secondly the concentration of the saturated solution under the same conditions in gram molecules of hydrogen sulfide per liter. The values shown represent the mean of several determinations at each concentration of hydrochloric acid,<sup>20</sup> checking within 0.2 to 0.3%.

TABLE I.—SOLUBILITY OF  $\text{H}_2\text{S}$  IN AQUEOUS SOLUTIONS OF  $\text{HCl}$ .  $25^\circ$ .

Normality of $\text{HCl}$ solution.	Absorption coefficient.	G. mols of $\text{H}_2\text{S}$ per liter.

<sup>a</sup>Accurate determinations of the solubility of  $\text{H}_2\text{S}$  in water at various temperatures have been made by Winkler, *Z. physik. Chem.*, 55, 350 (1906). Winkler's interpolated value for  $25^\circ$  is 2.257.

<sup>14</sup>It was first attempted to prepare  $\text{H}_2\text{S}$  by treating granulated  $\text{ZnS}$  with  $\text{HCl}$  in a Kipp generator. The  $\text{ZnS}$  available, however, varied too much in quality to give consistent results.

<sup>15</sup>Subsequent tests showed this to be unnecessary.

<sup>16</sup>Four wash-bottles were used; at the end of the experiments all except the first gave negative tests for chloride and carbonate.

<sup>17</sup>This was done in order to bring the gas to equilibrium with the final solution in advance, so avoiding concentration changes in this solution during determinations.

<sup>18</sup>With the apparatus employed it was found that absorption was complete in 2 or 3 hours.

<sup>19</sup>Pressure corrections were necessary for the vapor tension of the solution, the barometric pressure at the time of the experiment, and the average head of liquid over the portion of the solution titrated. The weight of 1 liter of  $\text{H}_2\text{S}$  under standard conditions was taken as 1.5392 g. (Baume and Perrot, *J. chim. phys.*, 6, 610 (1909).)

<sup>20</sup>The change in volume of the solution (and hence the change in  $\text{HCl}$  concentration) during absorption of the  $\text{H}_2\text{S}$  was found to be negligible.

The solubility curve evidently shows a minimum at about 0.4 *N* hydrochloric acid, and for concentrations of hydrochloric acid above 1.5 *N* the solubility of hydrogen sulfide is (contrary to the prevalent opinion) greater than in pure water. A still more rapid increase in solubility was found by Pollitzer<sup>21</sup> for hydrogen sulfide in aqueous solutions of hydrogen iodide; unfortunately the lack of data for concentrations of hydrogen iodide below 1 *N* obscures the position of the probable minimum.

Solubility determinations for hydrogen sulfide in other common strong acids (nitric and sulfuric) cannot be made, owing to their rapid oxidizing action. Even the presence of dissolved oxygen in the hydrochloric acid solutions here employed resulted in the slow precipitation of minute amounts of free sulfur from the solutions. This was minimized by boiling the solutions vigorously before standardization and exposing them to the air as little as possible before use.

The results of conductivity measurements<sup>22</sup> upon this system were entirely negative. Over a series of concentrations of hydrochloric acid ranging from 0.0074 *N* to 4.410 *N*, saturation of the solution with hydrogen sulfide produced no measureable change in the bridge reading.

### The System $\text{H}_3\text{BO}_3 : \text{HCl} : \text{H}_2\text{O}$ .

Standardized hydrochloric acid solutions were rotated with excess of powdered boric acid (purified by recrystallization from water) in the thermostat until saturation was reached. Samples of the clear solutions were pipetted out into tared porcelain crucibles and dried to constant weight at 60°. The boric acid content of the final solutions was thus directly obtained; the small changes in hydrochloric acid concentration involved in the increase of volume during solution of boric acid were corrected for by interpolated density determinations. Attempts to make a differential titration of the two acids in the final solution, as recommended by Herz,<sup>24</sup> were not satisfactory.

The results of conductivity determinations upon the saturated solutions, and upon hydrochloric acid solutions of the same concentrations, are included in the table below. Specific conductivities are expressed in reciprocal ohms throughout.

As will be seen from the figures in the second column,<sup>25</sup> a solubility minimum is again obtained, but only at a very high concentration (about 8.0 *N* hydrochloric acid). The conductivity changes due to the presence of dissolved boric acid are quite con-

<sup>21</sup> Pollitzer, *Z. anorg. Chem.*, 64, 121 (1909).

<sup>22</sup> A 3-meter Leeds and Northrup bridge was employed. Alternating current at 1000 cycles per second was obtained from a constant-speed high-frequency generator. The telephone receiver was tuned to the same frequency. The conductivity cell was of the Cantor type (Cantor, *Z. Elektrochem.*, 9, 922 (1903)).

<sup>23</sup> Preliminary trials with boric acid solutions of known concentration established the fact that this temperature was low enough to preclude appreciable loss of  $\text{H}_3\text{BO}_3$  by volatilization during evaporation.

<sup>24</sup> Herz, *Z. anorg. Chem.*, 33, 353 (1903).

<sup>25</sup> These values are not in accordance with those obtained by Herz (*loc. cit.*, p. 355) for the same system, although the form of the curve is precisely similar. The fact that Herz made no correction for changes in concentration of the solvent acid during solution of  $\text{H}_3\text{BO}_3$  is presumably the cause of this disagreement. Herz obtained the concentration of  $\text{H}_3\text{BO}_3$  in each solution from the difference between original and final titrations, and with very high concentrations of HCl a small total error involves a considerable error in  $\text{H}_3\text{BO}_3$ .

TABLE II.— $\text{H}_3\text{BO}_3$  IN AQUEOUS  $\text{HCl}$ . SOLUBILITY AND CONDUCTIVITY DATA.  $25^\circ$ .

<sup>a</sup>The values obtained by previous investigators are extremely discordant (see Seidell, "*Solubilities of Inorganic and Organic Compounds*," 1919, p. 153). The result here obtained, however, agrees fairly well with the more recent data (*e. g.*, 0.901 *N* (Herz) and 0.887 *N* (Ageno and Valla)).

siderable, as evidenced by the results in the last column. The decreases recorded cannot be entirely ascribed to viscosity changes in the solution, although direct experiment showed that the viscosities of boric acid solutions near the saturation point<sup>26</sup> are considerably higher than that of pure water, since the corresponding benzoic acid systems (see below) where the viscosity effect is negligible, exhibit exactly the same behavior. Their significance will be taken up in a later section.

### The System $\text{H}_3\text{BO}_3 : \text{HNO}_3 : \text{H}_2\text{O}$ .

The experimental procedure was exactly as in the previous system; solubility and conductivity results obtained are given in Table III below.

TABLE III.— $\text{H}_3\text{BO}_3$  IN AQUEOUS  $\text{HNO}_3$ . SOLUBILITY AND CONDUCTIVITY DATA.  $25^\circ$ .

15.81	0.1973	.....	.....	.....

<sup>26</sup>Experiments with a Bingham viscometer at  $25^\circ$  (carried out by Dr. J. J. Beaver) gave the following results:  $\text{H}_3\text{BO}_3$  0.6448 molar,  $d_4^{25}$  1.0096, relative viscosity 1.0603;  $\text{H}_3\text{BO}_3$  0.8 molar,  $d_4^{25}$  1.0160, relative viscosity 1.0833.

When the solubility results of the second column are plotted on a diagram, it becomes evident that the minimum on the curve is approximately at the last concentration examined—about 16.0 *N*. The decrease in specific conductivity of the solutions due to dissolved boric acid is similar to that shown in the preceding table.

### The System $C_6H_5.COOH:HCl:H_2O$ .

Solubility determinations were carried out as described in the case of boric acid above, the only difference (necessitated by the greater volatility of the benzoic acid) being that the solutions were allowed to evaporate to constant weight in a desiccator at room temperature. The residues gave no test for chloride.

The solubility and conductivity results obtained are tabulated as before. The correction in the hydrochloric acid concentration for volume change during solution is here inappreciable, owing to the low solubility of benzoic acid.

TABLE IV.—BENZOIC ACID IN AQUEOUS HCl. SOLUBILITY AND CONDUCTIVITY DATA. 25°.

9.522	0.0109	.....	.....	.....

\*Philip and Garner (*J. Chem. Soc.*, 95, 1466 (1909)) obtained the value 0.0277.

Once more a solubility minimum at a high concentration of solvent acid (approximately 8.5 *N*) is indicated. The decrease in conductivity due to the presence of the solute acid is, as in the case of the boric acid systems, quite considerable.

### The System $C_6H_5.COOH:HNO_3:H_2O$ .

Measurements for this system were not extended beyond 5.0 *N* nitric acid, since it was desired to avoid nitration effects.<sup>27</sup>

TABLE V.—BENZOIC ACID IN AQUEOUS  $HNO_3$ . SOLUBILITY AND CONDUCTIVITY DATA. 25°.

Normality of $HNO_3$ soln.	Normality of dissolved $C_6H_5.COOH$ .	Spec. cond. of $HNO_3$ soln.	Spec. cond. of final soln.	Decrease due to $C_6H_5.COOH$ .

3.883	0.0277	0.5657	0.5573	0.0084
4.784	0.0284	.....	.....	.....

The minimum in the solubility curve is here at a much lower concentration of the solvent acid—about 0.2 *N*. The conductivity results, however, again closely resemble those of the corresponding hydrochloric acid system.

### The System C<sub>6</sub>H<sub>4</sub>OH.COOH : HCl : H<sub>2</sub>O.

This system has already been investigated by Kendall<sup>28</sup> and by Knox and Richards,<sup>29</sup> the results here presented are in fair agreement with their values. The experimental procedure was essentially that followed in the case of benzoic acid systems.

TABLE VI.—SALICYLIC ACID IN AQUEOUS HCl. SOLUBILITY AND CONDUCTIVITY DATA.

<sup>a</sup> Increase in specific conductivity

<sup>b</sup> The previous values for the solubility in pure water are 0.01634 (Kendall) and 0.01613 (Knox and Richards).

A very flat minimum in the solubility curve is obtained at about 6.0 *N* hydrochloric acid; the conductivity results, however, differ from those of the previous tables in that an increase, instead of a decrease, is induced by the solute acid. This increase is negligible at low concentrations, but becomes very marked above 2.0 *N* hydrochloric acid.

### The System C<sub>6</sub>H<sub>4</sub>OH.COOH : HNO<sub>3</sub> : H<sub>2</sub>O.

The solubility curve for this system could not be carried very far, owing to rapid nitration of the salicylic acid at concentrations of nitric acid above 0.5 *N*.

<sup>28</sup> Kendall, *Proc. Roy. Soc.*, [A] 85, 204 (1911).

<sup>29</sup> Knox and Richards, *loc. cit.*

TABLE VII.—SOLUBILITY OF SALICYLIC ACID IN AQUEOUS SOLUTIONS OF  $\text{HNO}_3$ .

Normality of $\text{HNO}_3$ soln.	Normality of dissolved salicylic acid.	Normality of $\text{HNO}_3$ soln.	Normality of dissolved salicylic acid.
0.0	0.0162	0.2408	0.0141
0.0109	0.0149	0.5514	0.0150
0.0420	0.0140	1.019	0.0184
0.0807	0.0139	.....	.....

The minimum on the curve is here at a very low concentration of solvent acid—less than 0.1 *N* nitric acid. Above 0.5 *N* the results are only approximate, since the residues obtained were appreciably nitrated. For this reason no conductivity determinations were attempted on this system.

### Discussion of Solubility Results.

The solubility curves for a number of systems of the general type  $\text{HX}:\text{HY}:\text{H}_2\text{O}$  are represented in Figs. 1, 2 and 3 below. In the first two diagrams the solvent acid is hydrochloric. The curves for the 4 solute

Fig. 1.

acids here investigated are shown, and a selection of the data from previous articles<sup>30</sup> has been added to assist in the discussion. In the third diagram

<sup>30</sup> Most of the data are due to Knox and Richards (*loc. cit.*). Results by Masson (*J. Chem. Soc.*, 101, 103 (1912)); Stepanov (*Ann.*, 373, 221 (1910)); Geffcken (*Z. physik. Chem.*, 49, 254 (1904)), and Herz (*Z. anorg. Chem.*, 34, 205 (1903)) are also included.

the solvent acid is acetic, a weak acid. To render all results directly comparable, the solubilities are expressed throughout as ratios of the solubility at any given concentration to the solubility in pure water.

At first glance it seems hopeless to attempt to draw any significant general conclusions from the course of the curves; they appear to run almost at random. Closer inspection, however, enables us to note the following facts.

Fig. 2.

(1) When the solvent acid is strong, the sudden initial "ionic dip" in solubility is very marked in all cases except (a) when the solute acid is very weak, or (b) when the solute acid is very soluble in pure water. In Fig. 1 benzoic acid falls under (a),  $\beta$ -naphthalene sulfonic acid under (b). The remaining acids all show a very sharp solubility decrease when hydrochloric acid is first added. That this decrease is due to the suppression of their ionized fractions is evident from the variation in its magnitude as the strength of the solute acid is changed. Thus for picric acid the decline is exceedingly abrupt; it becomes less and less violent as we proceed through the weaker nitrobenzoic acids, until for benzoic acid it is almost absent. With this acid (see also succinic acid in Fig. 2) the solubility falls off regularly as the concentration of hydrochloric acid increases, there is only a trace of a sharp introductory drop. This is only natural, and since there is only a very small ionic portion to repress in such weak acids, inversely, the regularity of the decline in the case of the more soluble stronger acids (e. g.,  $\beta$ -naphthalene sulfonic in Fig. 1, oxalic and trichloro-

lactic in Fig. 2) is to be ascribed to the fact that their ionic concentrations in pure water are too high to be annihilated suddenly by small additions of hydrochloric acid: the suppression of their ionized fractions is consequently a gradual process.

(2) When the solvent acid is weak, the ionic dip is (as might be expected) much less frequently recognizable. In Fig. 3 oxalic acid shows a brief initial solubility decrease; more distinct evidence would, no doubt, be given by less soluble strong acids (*e.g.*, picric) in acetic acid solutions, but confirmatory experimental data are lacking.

Fig. 3.

(3) When the solvent acid is strong, the decline in solubility persists in all cases well beyond the "constant undissociated value" postulated by Nernst. Thus the solubility ratios for weak acids such as boric acid and benzoic acid fall below 0.4 at high concentrations of hydrochloric acid, although their saturated solutions in pure water are only very slightly ionized. Similarly the solubilities of transition acids (*e.g.*, salicylic, *o*-nitrobenzoic) undergo an abnormal decrease, as indicated in a previous article,<sup>31</sup> while that for  $\beta$ -naphthalene sulfonic acid approaches very closely to zero. This characteristic in the curves must be ascribed to extensive hydration of the solvent acid (hydrochloric acid), as indicated in the introductory sections.<sup>32</sup>

<sup>31</sup> Kendall, *Proc. Roy. Soc.*, [A] 85, 217 (1911).

<sup>32</sup> The solubility of a weak base (ammonia) in water is similarly depressed to an abnormal extent on addition of a strong base (potassium or sodium hydroxide), as has been shown by Abegg and Riesenfeld (*Z. physik. Chem.*, 40, 84 (1902)). In the

(4) When the solvent acid is strong, the excessive decline is in all cases but one followed, at high concentrations, by an increase in solubility. The single exception is  $\beta$ -naphthalene sulfonic acid in hydrochloric acid; this must be regarded as a typical example of a system containing 2 strong acids.<sup>33</sup> The change in direction in all other systems<sup>34</sup> can be explained only on the basis of compound formation between the two acids present. Its late appearance indicates that such compounds are in general, highly dissociated in aqueous solution, but this again is only to be expected, since water is a competing base, stronger and present in much higher concentration. Hydration will therefore outbalance compound formation between the acids until the water concentration is considerably reduced. No connection can be established at present between the position or the sharpness of the minimum and the relative strengths of the two acids. We should anticipate that the weaker the solute acid the greater its tendency to combine with hydrochloric acid, but even such weak acids as hydrogen sulfide<sup>35</sup> and boric acid give a very flat minimum, while stronger acids such as 3,5-dinitrobenzoic and oxalic show a sharp turn in the curve. The very variable solubilities of the different solute acids in pure water certainly introduce complicating factors here for which it is difficult to correct,<sup>36</sup> and more work is evidently necessary to elucidate the irregularities exhibited.

(5) When the solvent acid is weak, the course of the curves is extremely variable (see Fig. 3). Changes in internal pressure and in the average molecular volume of the solvent here seem to be the predominant factors in affecting solubilities, so long as the solute acid is also weak. When the solute acid is strong, we should expect compound formation to be indicated by a rising portion on the solubility curve. Data for this type are, however, not very plentiful. Boric acid, which gives a falling curve in acetic acid solutions, does show steadily increasing solubility values with

same way, the solubility of a non-electrolyte in water is lowered by the presence of a hydrated second solute. Thus Geffcken (*ibid.*, 49, 268 (1904)) found the solubility of hydrogen to fall off rapidly in the presence of strong acids ( $\text{H}_2\text{SO}_4$ ,  $\text{HNO}_3$ ,  $\text{HCl}$ ). Transition acids (chloro-acetic) induce a smaller decrease; weak acids (acetic) have still less effect. Compare also Philip, *Trans. Faraday Soc.*, 3, 140 (1907).

<sup>33</sup> Other systems of a similar character, with the same type of curve, are  $\text{HCl}$  in  $\text{H}_2\text{SO}_4$  solutions (Coppadoro, *Gazz. chim. ital.*, II 39, 625 (1909)), and  $\text{HIO}_3$  in  $\text{HNO}_3$  solutions (Groschuff, *Z. anorg. Chem.*, 47, 344 (1905)).

<sup>34</sup> The curves given by the gaseous solutes are of substantially the same type as those given by solid acids. No marked difference in behavior, moreover, can be noted between inorganic and organic acids.

<sup>35</sup> Baume and Georgitses (*J. chim. phys.*, 12, 242 (1914)) did not isolate any compounds from the system  $\text{HCl}:\text{H}_2\text{S}$ , but found that a continuous series of solid solutions was formed.

<sup>36</sup> Compare Knox and Richerds, *op. cit.*, p. 530.

stronger organic acids such as oxalic,<sup>37</sup> lactic<sup>38</sup> and tartaric,<sup>39</sup> but this may be due in the case of the last two acids to a special effect, as will appear in the following section.

### Discussion of Conductivity Results.

Compound formation between a weak acid and a strong acid in aqueous solution may be predicted to bring about a decrease in specific conductivity at the lower concentrations here examined,<sup>40</sup> since the mobilities of the ions of the resultant *salt*<sup>41</sup> will not equal those of the strong acid which have disappeared in its formation. At the higher concentrations, on the other hand, where the salt is produced mainly at the expense of non-ionized acid, the decrease will tend to diminish.

This anticipated behavior is actually realized in Tables II to V of this paper, *i. e.*, for solutions of boric and benzoic acids in hydrochloric and nitric acids. The specific conductivity changes in all 4 series, due to the presence of the dissolved weak acid, are substantially as described above. At low concentrations the decrease is roughly proportional to the product of the concentrations of the two acids. It reaches a maximum at approximately 2.0 *N* concentration of strong acid and subsequently exhibits declining values.

Not all of those systems, however, which indicate the existence of compound formation by the solubility curves give similar conductivity results. Thus the conductivity of hydrochloric acid solutions is unaffected, within the limits of experimental error, by the presence of hydrogen sulfide. In the same way, it was found that saturation of hydrochloric or nitric acid solutions with other gases of a weakly acidic nature—such as carbon dioxide or acetylene—involved no measurable change in their specific conductivities, although very careful determinations were made and all possible precautions taken to establish small variations.<sup>42</sup> No theoretical reason for this uniformity of negative results with gaseous solutes can at present be suggested.

<sup>37</sup> Herz, *Z. anorg. Chem.*, **66**, 93 (1910). Oxalic acid is also more soluble in boric acid solutions than in pure water.

<sup>38</sup> Mueller and Abegg, *Z. physik. Chem.*, **57**, 514 (1906).

<sup>39</sup> Herz, *Z. anorg. Chem.*, **70**, 71 (1911).

<sup>40</sup> At extremely low concentrations of strong acid, it must be noted, addition of the weak acid involves a small *increase* in specific conductivity, since its ionization will not be significantly repressed. This effect was confirmed for all systems at concentrations of HCl or HNO<sub>3</sub> below 0.005 *N*, but since the present discussion is restricted to much higher concentrations, further consideration of this point is not necessary here.

<sup>41</sup> That addition compounds of this type exhibit electrolytic dissociation in solution has been proved by Rördam, *THIS JOURNAL*, **37**, 557 (1915).

<sup>42</sup> At extremely low concentrations of the strong acid, as explained in the preceding note, a very small increase in specific conductivity is obtained. (Compare Whetham, *Z. physik. Chem.*, **55**, 200 (1906); Drucker, *Z. Elektrochem.*, **13**, 81 (1907)).

In solutions of salicylic acid in hydrochloric acid, an inverse effect— increase in specific conductivity—is actually apparent. If this increase were most noticeable at low concentrations of hydrochloric acid, it might be explained as due to the persistence of ionized salicylic acid in the solutions. At low concentrations, however, the effect is practically absent; it is only at higher concentrations of hydrochloric acid, where the concentration of salicylic acid has decreased far beyond its "constant undissociated value," that the increase in specific conductivity becomes appreciable. It becomes necessary, therefore, to seek an alternative explanation for the anomalous behavior of this system.

Magnanini<sup>43</sup> found that addition of small amounts of polyhydric alcohols increased the specific conductivity of boric acid solutions, owing to the formation of more readily ionized complexes. He also discovered that while addition of boric acid to aqueous solutions of organic acids caused no change in specific conductivity if these acids contained no hydroxyl group, yet a noticeable increase was obtained with aliphatic acids possessing an hydroxyl group in the  $\alpha$ -position and with aromatic acids possessing an hydroxyl group in the *ortho* position. More extensive investigations in this field have recently been made by Böeseken and his co-workers.<sup>44</sup> In view of their results, which indicate that the complexes formed by boric acid and suitable weak organic acids are comparable in strength with the strongest inorganic acids, it would seem logical to ascribe the increase here observed in the system salicylic acid (*o*-hydroxy-benzoic acid)—hydrochloric acid at high concentrations to the formation of an especially highly-ionized complex of a similar character. The examination of additional systems of this type by the conductivity method is obviously necessary, however, before final conclusions can be drawn.

Combination of solubility and conductivity data furnishes us, it may be noted, with a very strong method of attacking the question of the laws governing compound formation in systems of the type weak acid (solute): strong acid (solvent), here particularly studied. From the solubility results we can establish the effect of the strong acid on the weak acid, from the conductivity results the effect of the weak acid on the strong acid. The correlation of the data from sufficient systems should enable us, therefore, to obtain some insight into what is at present a very confused portion of the field of aqueous solutions. In all such investigations, however, the effect of the third component—water—upon all of the equilibria involved must, in addition, be much more intensively examined.

<sup>43</sup> Magnanini, *Gazz. chim. ital.*, 20, 448 (1890); 21, 215 (1891); 22, 541 (1892); 23, 197 (1893).

### Summary.

The solubility curves for hydrogen sulfide, boric acid, benzoic acid and salicylic acid in aqueous solutions of hydrogen chloride, and for the last three of the above mentioned weak acids in aqueous solutions of nitric acid, have been determined. The changes in the specific conductivities of the solvent acids, due to the presence of the weak acids in solution, have also been investigated.

The results obtained, together with those of previous investigators, have been critically discussed in connection with the rule, established in an earlier article, that compound formation between acids in pairs increases in extent with increasing diversity of acidic strengths. The predicted and observed solubility curves for systems of various types have been compared, and satisfactory agreement, in general, has been obtained. The conductivity results also fall into line in most cases. Further experimental work, however, is required to elucidate certain abnormalities in particular systems. To establish the rules here outlined upon a final basis, a better understanding of the part played by the third component—water—is also necessary.

## A MODIFIED METHOD FOR THE DETERMINATION OF IRON AND VANADIUM AFTER REDUCTION BY HYDROGEN SULFIDE.<sup>1</sup>

BY G. E. F. LUNDELL AND H. B. KNOWLES.

Received March 29, 1921.

### I. Introduction.

Some time ago the authors had occasion to determine whether uranyl compounds suffered reduction when their ammoniacal solutions were saturated with hydrogen sulfide and then slightly acidified with sulfuric acid and boiled. Experiments were accordingly carried out which demonstrated that while there was no reduction of uranium, some compound was formed in sufficient amount to consume appreciable quantities of a potassium permanganate solution. It was suspected that this reduction was occasioned by polythionic acids which had been formed during the course of the reactions and it was realized that if such was the case, the observation would be of importance in operations dealing with sulfide reductions in general and those of iron and vanadium in particular.

<sup>1</sup> Published by permission of the Director of the Bureau of Standards.

A search of the literature revealed considerable differences in the methods recommended for hydrogen sulfide reductions and in three researches direct evidence was found that the method was subject to error. The conclusions reached in these researches have been practically buried because one research was published under the broad title "The Determination of Iron in Iron Ores" in a foreign journal, another appeared under the title "Contributions to the Volumetric Determination of Antimony, Tin, Titanium, Iron and Uranium" in a privately printed doctorate dissertation, while the third was unpublished.

## II. Historical.

Fresenius-Cohn<sup>2</sup> specify that the cold ferric solution containing a liberal excess of sulfuric acid be reduced by hydrogen sulfide in a flask two-thirds filled until the color disappears and the passage of gas be then continued for at least 10 minutes. The solution is boiled until reduced to  $\frac{1}{2}$  its first volume, and finally diluted with cold water until the flask is nearly filled.

Treadwell-Hall<sup>3</sup> outline two procedures as follows.

(1) The solution of the ferric sulfate containing 10% (by volume) of sulfuric acid is boiled, reduced with hydrogen sulfide until colorless, and the boiling then continued as a current of carbon dioxide is swept through to expel the hydrogen sulfide. (2) The cold sulfuric acid solution (acidity not stated) is saturated with hydrogen sulfide, heated to boiling, and filtered into a flask containing carbon dioxide. The filtrate is boiled as a current of carbon dioxide is passed through and the solution finally cooled in a stream of the gas. In addition it is stated on page 609, "By means of the latter (hydrogen sulfide) the ferric salt is completely reduced, independent of how little or how much free acid is present in the solution."

Gooch<sup>4</sup> directs that the acidified iron solution be boiled, treated to complete reduction with hydrogen sulfide, and the gas expelled by boiling with carbon dioxide.

Scott<sup>5</sup> advocates the use of the filtrate from the hydrogen sulfide group separation, after boiling out hydrogen sulfide.

Mellor<sup>6</sup> merely states that "hydrogen sulfide can be used for reducing the iron," and is obviously not enthusiastic concerning its use.

Washington<sup>7</sup> specifies that the gas be passed through the cold sulfuric acid solution, (acidity not defined), the solution filtered, boiled while carbon dioxide is passed through, and cooled under the same gas.

<sup>6</sup> Mellor, "A Treatise on Quantitative Inorganic Analysis," C. Griffin and Co., 1, p. 191 (1913).

<sup>7</sup> Washington, "The Chemical Analysis of Rocks," John Wiley and Sons, 3rd Ed., pp. 163-165.

Hillebrand<sup>8</sup> directs that the cooled solution containing 1.5 to 2.5% by volume of sulfuric acid be treated with hydrogen sulfide, boiled with continued passage of the gas until the sulfur is coagulated, cooled during continued passage of the gas, filtered, treated again with hydrogen sulfide, then boiled and cooled while a current of carbon dioxide is passed through the solution.

R. Fresenius<sup>9</sup> in an article on the determination of iron in iron ores by the Reinhardt method, noted that filtrates from the hydrogen sulfide separation of copper from iron were apt to give high values when subsequently titrated with permanganate. He reached the conclusion that satisfactory results could be obtained by the complete oxidation with permanganate of the hydrogen sulfide filtrate, followed by reduction with stannous chloride and final titration in accordance with the Reinhardt method.

Boller<sup>10</sup> quoted a private communication from Dr. Herrmann to Dr. Treadwell to the effect that values obtained by Hillebrand's method were too high. Work subsequently done by Boller demonstrated that 500 cc. of 1*N* sulfuric acid solution, treated with 1.0 cc. of a saturated sulfur dioxide solution and then as in Hillebrand's method required 2.9 cc. of 0.01 *N* permanganate solution; practically the same values were obtained with sulfur present as with sulfur filtered off. Boller demonstrated by experiments with purified sulfur treated under like conditions that the reducing compounds obtained above were not entirely due to polythionic acids formed by the action of hydrogen sulfide on sulfur dioxide. Further tests of the method carried on with a standard solution of ferric chloride in hydrochloric acid with final titration in the presence of Zimmermann-Reinhardt solution gave results which averaged 0.1040 g. of iron with no filtration of sulfur, 0.1041 g. of iron with filtration of sulfur through paper, and 0.1040 g. of iron with filtration of sulfur through a Gooch crucible, as against a true value of 0.1020 g. of iron.

McBride,<sup>11</sup> in a series of experiments dealing with the reduction of iron by hydrogen sulfide, arrived at the following conclusions.

"It should be noted that the limits of acidity at the time of reduction are given as 2.00 to 2.5%. Any variation from these limits introduces an error. If more than 2.5% volume of free sulfuric acid is present the iron cannot be completely reduced. The use of less than 2.0% by volume of free acid, however, is not permissible, as with the less strongly acidified solution, some compounds having a reducing action on potassium permanganate are formed which are not removable by the boiling with carbon dioxide before titration. The smaller the amounts of free acid, the higher the amount of iron indicated by the titration."

The above citations, particularly the last three, demonstrated the need of an investigation of the hydrogen sulfide reduction and full publicity of the results obtained. This is all the more important since the method is often recommended and widely used on account of such considerations as enumerated by Washington.<sup>7</sup> "This (hydrogen sulfide) commends itself on account of its certainty and rapidity of action, its easy and complete removability, and still more by the fact that it has no reducing action on the titanic and platinic sulfates that are always present (in rock analysis);" and "Hydrogen sulfide is much more readily obtainable than sulfur dioxide—a minor, but practically important consideration."

### III. Experimental.

Preliminary experiments demonstrated that compounds which were removed neither by filtration nor by prolonged boiling in a stream of carbon dioxide, and which subsequently reduced potassium permanganate, were formed in either hot or cold solutions: (1) when a dilute solution of sulfurous acid was treated with hydrogen sulfide; (2) when a freshly-prepared ammonium sulfide solution containing a very small amount of polysulfide was acidified with sulfuric acid; and (3) when a sulfuric acid solution of potassium permanganate was treated with hydrogen sulfide. That the reduction was not due to sulfur dioxide or hydrogen sulfide was demonstrated by the fact that aliquot portions of the solutions did not react with 0.1 *N* iodine solution.

It seemed entirely probable that similar reducing compounds would be formed in any reduction involving the use of hydrogen sulfide. Table I presents data which show the results that are to be expected in hydrogen sulfide reductions of iron carried out under varying conditions of acidity, volume of solution, temperature, and time of reduction.

Counterpoised weight burets were used throughout and corrections made in the usual manner for reagents and end-points. The iron solution was prepared from highest purity ferrous ammonium sulfate and its iron titer taken as an average of closely agreeing values found by reduction with sulfur dioxide, reduction in a Jones reductor, double gravimetric precipitations by ammonia with final correction for silica and precipitation with cupferron followed by silica correction. The permanganate solution was prepared with the necessary precautions and standardized by means of the Bureau of Standards sodium oxalate by the method of McBride.<sup>12</sup> The hydrogen sulfide used was passed through solutions of sodium hydrogen carbonate and blank runs demonstrated that it contained no products which subsequently consumed permanganate. Reductions were performed in glass wash-bottles in order that no organic material might be introduced.

All reduced iron solutions were tested with potassium thiocyanate and in Table I reductions were complete unless otherwise indicated. Since preliminary experiments demonstrated that sulfur alone in sulfuric acid solution was without effect on permanganate, titrations were performed in its presence unless otherwise specified.

A study of the data presented in Table I demonstrates that: (1) The hydrogen sulfide reduction method for iron ordinarily gives high values in completely reduced solutions. This holds true in all acidities, in reductions in cold or boiling solutions and in the presence or absence of sulfur. The high values are not in direct ratio to the quantity of iron

<sup>d</sup> Sulfur filtered off before final reduction.

<sup>e</sup> CO<sub>2</sub> passed into cold sol. for 145 min. and into boiling soln. for 45 min.

<sup>f</sup> Sulfur filtered off before final reduction.

<sup>g</sup> Reduced sol. contained Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>.

<sup>h</sup> Reduced sol. contained no Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>.

<sup>i</sup> Reduced sol. contained Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>.

<sup>j</sup> CO<sub>2</sub> passed into cold sol. for 145 min. and into boiling sol. for 45 min. Reduced sol. contained Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>.

involved. (2) A low initial volume (100 cc.) and moderate acidity (2 to 2.5% by volume) is desirable. (3) Complete reduction in cold solution is slow, and in boiling solutions impossible in acidities much over 1%, especially in solutions of large volume. A favorable procedure consists in reduction in cold solution for 30 minutes, followed by warming to the boiling point for 15 minutes. (4) Complete reduction can sometimes be had

by the latter procedure in sulfuric acid concentrations as high as 10% by volume. Complete reduction in 5% by volume is easily attained.

Table II lists determinations carried out under the following conditions which were based for the most part on a study of the experiments listed in Table I: volume of solution, 100 cc.; acidity, 2.5% sulfuric acid by volume; hydrogen sulfide reduction 30 minutes in cold solution and 15 minutes as solution is heated to boiling; addition of 15 cc. of sulfuric acid (1:1); boiling for 30 to 60 minutes to a volume of approximately 50 cc. as a stream of carbon dioxide is bubbled through; cooling under the same conditions; dilution to 200 cc. with cold distilled water; and titration with standard permanganate solution. In some cases the separated sulfur was filtered off after the hydrogen sulfide treatment and after the reduced solution was cooled somewhat. The filtrate was then again treated with hydrogen sulfide for 10 minutes before proceeding as above described. The modified method differs from the method given by Hillebrand<sup>13</sup> in that the volume of the solution is fixed at 100 cc., the solution is not boiled as hydrogen sulfide is bubbled through and the acidity of the solution is raised before the expulsion of the hydrogen sulfide. The method differs from that advocated by McBride<sup>14</sup> in the latter two respects and also by the expressed limitation of the solution to small volume.

TABLE II.—DETERMINATION OF IRON BY THE MODIFIED HYDROGEN SULFIDE METHOD.

Iron.		Error.	CO <sub>2</sub> passed into the boiling sol. (minutes).	Remarks.
Taken.	Found.			
G.	G.	G.		
0.0129	0.0132	+0.0003	30	
0.1765	0.1766	+0.0001	30	Acidity at end of boiling was 25%.
0.00748	0.00756	+0.00008	60	Acidity at end of boiling was 33%.
0.0266	0.0267	+0.0001	60	Acidity at end of boiling was 33%.
0.1253	0.1253	0.0000	50	Sulfur filtered off before final
0.00442	0.00455	+0.00013	60	reduction.
				Sulfur filtered off before final
0.0254	0.0256	+0.0002	60	reduction.
				Sulfur filtered off before final
0.1310	0.1313	+0.0003	60	reduction.

The data in Table II demonstrate that while the modified method still gives values which are slightly high, determinations by the method are sufficiently accurate for most purposes. Incidentally, it is seen that ferrous sulfate is not oxidized upon boiling in a solution containing 33% (by volume) of sulfuric acid. The authors did not carry out experiments

<sup>13</sup> Hillebrand, "The Analysis of Silicate and Carbonate Rocks," U. S. Geol. Survey, *Bull.* 700, pp. 119-20.

<sup>14</sup> Unpublished.

dealing with slight variations of the modified method on account of the ease with which the specified conditions can be met.

Table III presents data obtained in the determination of vanadium by the ordinary hydrogen sulfide reduction and also by the modified method. The vanadium solution was standardized by sulfur dioxide reduction and also by reduction in a Jones reductor with ferric alum and phosphoric acid in the receiver.

TABLE III.—DETERMINATION OF VANADIUM BY THE ORDINARY AND BY THE MODIFIED HYDROGEN SULFIDE METHOD.

Vanadium.					
Taken. G.	Found. G.	Error. G.	Volume of solution cc.	H <sub>2</sub> SO <sub>4</sub> (% by Volume).	Remarks.
0.0469	0.0482	+0.0013	250	0.5	Ordinary Method.
0.0419	0.0428	+0.0009	250	0.5	Ditto, sulfur filtered off.
0.0430	0.0431	+0.0001	100	2.5	Modified Method.
0.0469	0.0469	0.0000	100	2.5	Ditto.

It is apparent that high results are to be expected in ordinary hydrogen sulfide reductions of vanadium and that satisfactory values are obtained with the modified method. Hillebrand<sup>15</sup> has noted the former and states "One or two checks (on vanadium) are always to be made by reducing again (after titration of the solution reduced by hydrogen sulfide) by means of a current of sulfur dioxide, boiling this out again and repeating the titration. The latter results are apt to be a very little lower than the first and are to be taken as the correct ones." The higher value in the first titration was ascribed by Hillebrand to the extraction of oxidizable matter from the filter paper used to filter off sulfur and sulfides, as noted by McBride and Scherrer,<sup>16</sup> and recently, under more severe conditions, by Myhill.<sup>17</sup>

As sulfur alone is without effect on permanganate and the sulfur in Expt. 2 was filtered off on a filter paper freshly washed with acid it is certain that the higher values cannot be ascribed entirely to oxidizable extracts from filter papers.

#### IV. Conclusions.

Published methods for the reduction of iron by hydrogen sulfide are faulty in either of two respects: (1) complete reduction is impossible or, (2) when reduction is complete, other oxidizable compounds are formed

<sup>15</sup> *Op. cit.*, p. 188.

<sup>16</sup> McBride and Scherrer, *THIS JOURNAL*, 39, 928 (1917).

<sup>17</sup> Myhill, *Chem. Age*, 4, 151 (1921).

which cause high values.<sup>18</sup> The second statement also applies to the determination of vanadium.

The hydrogen sulfide method for iron or vanadium as herein modified is sufficiently accurate for all ordinary work.

In case the highest accuracy is desired, the sulfur dioxide method is recommended. Sulfur dioxide reduces vanadium to the quadrivalent condition and does not reduce quadrivalent titanium. Unfortunately it reduces platinum to the bivalent condition and also reduces various members of the hydrogen sulfide group; consequently when platinum (as is usually the case in rock analysis, owing to the platinum ware employed) or other members of the hydrogen sulfide group are present, a modification of the method already used in the determination of vanadium by Hillebrand<sup>19</sup> is called for, namely, precipitation with hydrogen sulfide in acid solution, separation of sulfides by filtration, boiling out of hydrogen sulfide in the filtrate, complete oxidation by 10% permanganate solution and final reduction with sulfur dioxide gas. The following notes and precautions, taken for the most part from the work of Hillebrand<sup>20</sup> are of interest in the later operation.

The direct use of a solution of sulfur dioxide or of an alkali sulfite is inadmissible unless these have been freshly prepared, for after a lapse of time they contain other oxidizable bodies than sulfurous acid or a sulfite.

Sulfur dioxide is most conveniently obtained from a cylinder of the liquefied gas or, in default of this, by heating a flask containing a solution of sulfur dioxide, or of a sulfite to which sulfuric acid has been added.

Reductions with this gas require low initial acidities, and hydrochloric acid—chloride solutions are reduced more rapidly than sulfuric acid—sulfate solutions; in the former case a titration with permanganate requires previous addition of titrating solution as in the Zimmermann-Reinhardt method.

Reduced solutions containing sulfur dioxide should not be allowed to stand for over 24 hours lest other oxidizable bodies be formed.

The expulsion of the last trace of sulfur dioxide is said to be accomplished more effectively by boiling with simultaneous passage of a rapid current of carbon dioxide.

The authors have not made any serious attempts to isolate and identify the oxidizable compound or compounds which are formed in hydrogen

<sup>18</sup> It is to be borne in mind that these oxidizable compounds are quite stable and consequently may cause trouble in any quantitative operation calling for a final oxidation as, for instance, where the hydrogen sulfide solution is boiled to expel the gas and then reduced by stannous chloride or in a Jones reductor preliminary to titration with dichromate or permanganate. The obvious remedy lies in complete oxidation before the final reduction.

<sup>19</sup> Hillebrand, *op. cit.*, p. 168.

<sup>20</sup> Hillebrand, *ibid.*, p. 186.

sulfide reductions. It is believed that they are polythionic acids and it has been noted that (1) they are quite stable upon boiling with sulfuric acid in concentrations as high as 33% by volume; (2) they are volatile upon prolonged boiling; (3) the volatilized compounds do not react with iodine solution; and (4) their dilute solutions give with silver nitrate solution a yellowish-brown coloration.

### V. Summary.

1. The determination of iron or of vanadium by reduction with hydrogen sulfide followed by titration with permanganate or dichromate ordinarily gives high values.

2. These high values are not due to the presence of sulfur and persist in spite of the complete expulsion of hydrogen sulfide and the avoidance of organic matter extracted from filter paper. They may be ascribed to polythionic acids which are not destroyed by boiling in moderately conc. sulfuric acid solution and which are volatilized slowly from dilute and more rapidly from concentrated solutions.

3. Reasonably accurate determinations may be made by restricting the original solution to 100 cc. and proceeding by the described modified method.

4. For accurate determinations of iron and vanadium in solutions containing platinum (as in rock analysis) a preliminary separation of the hydrogen sulfide group, followed by expulsion of the gas, complete oxidation with permanganate and reduction with sulfur dioxide is recommended.

The authors desire to express to Dr. W. F. Hillebrand their sincere appreciation of his aid and counsel.

## THE CONDUCTANCE OF SOLUTIONS OF TERNARY ELECTROLYTES IN PROPYL ALCOHOL.

BY CHARLES A. KRAUS AND JOHN EGBERT BISHOP.

Received March 30, 1921.

### I. Introduction.

Our knowledge of the ionization process of ternary electrolytes in non-aqueous solvents is very limited and even in the case of aqueous solutions the nature of the ionization process for these substances is uncertain. If intermediate ions are formed according to the equation

which, in turn, break down according to the equation

then it is not possible to determine the equilibrium in the solution by means

of conductance measurements alone. In view of the fact that the laws governing solutions of strong electrolytes are not known, other properties of these solutions cannot be employed to supply the additional relation necessary to obtain a solution of the problem. In the case of weak acids and bases it has been shown that intermediate ions are formed. Noyes and Eastman<sup>1</sup> have established that a similar process takes place in solutions of sulfuric acid. In the case of salts, however, no definite evidence exists to show that intermediate ions are formed, although Harkins,<sup>2</sup> from the effect of various electrolytes upon the solubility of difficultly soluble salts of higher type, has reached the conclusion that intermediate ions do, in fact, exist.

Schlamp<sup>3</sup> measured the conductances of solutions of sodium iodide, lithium chloride and calcium chloride in propyl alcohol. Völlmer<sup>4</sup> drew from Schlamp's results the conclusion that calcium chloride behaves like a binary electrolyte in propyl alcohol solution, its conductance curve lying intermediate between those for lithium chloride and sodium iodide and being approximately parallel to them. It seemed worth while to measure the ionization of a number of ternary electrolytes in propyl alcohol in order to determine whether Schlamp's results and Völlmer's conclusions therefrom could be substantiated. Incidentally, it may be stated that, in fact, Schlamp's values for the conductance of calcium chloride solutions lie below those for lithium chloride and sodium iodide and not between them.

## II. Apparatus and Materials.

The conductance cell employed consisted of a cylindrical tube about 40 cm. long, having a capacity of approximately 200 cc. It was provided with platinized electrodes at the bottom and with a neck and a ground-glass stopper at the top. This neck was bent at an angle of 60° with the axis of the cell in order to facilitate the process of mixing the solutions.

The cell constant was determined by means of 0.02 *N* and 0.01 *N* solutions of potassium chloride, whose specific conductance values at these concentrations were assumed to be 0.002397 and 0.001225 respectively. The constant of the cell was determined to be 0.2049 at 18.00°.

Propyl alcohol was prepared by repeated fractionation and was finally dehydrated by means of metallic sodium. Immediately before introducing into the cell, a small amount of sodium was added to the alcohol. It was then distilled directly into the conductance cell, the intermediate fraction only being used. The specific conductance of the pure solvent varied between  $1.3$  and  $1.7 \times 10^{-7}$ . The value of the specific conductance of the solvent was in each case subtracted from that of the solution, the differ-

ence being assumed to give the true value for the specific conductance of the electrolyte in solution.

The salts employed were anhydrous calcium nitrate and the hexahydrate of magnesium nitrate. The calcium nitrate was imported c. p. material and was further purified by two crystallizations from doubly distilled water and finally from conductivity water. Contrary to the statement made in Abegg's "*Handbuch der Anorganischen Chemie*," it was not found possible to dehydrate the crystallized salt at 160° in air. At the end of 3 days, so much water of crystallization remained that the entire mass was still completely liquid. The salt was then placed in a desiccator over phosphorus pentoxide which was then evacuated to a pressure as low as 0.001 mm. At the end of 5 days an appreciable amount of water still remained in the salt. It was then placed in one arm of an H-tube, the other arm of which was filled with phosphorus pentoxide. A plug of glass wool was placed between the two arms to prevent contamination of the salt. The tube was exhausted to a pressure below 0.001 mm. and sealed off. The limb containing the salt was then heated for 2.5 days in a water-bath at 100°; that containing the phosphorus pentoxide remaining at room temperature. At the end of that time no trace of water could be found.

The magnesium nitrate was an imported grade "For Analysis" and no further purification was attempted. It was at first intended to dehydrate this salt also, but the attempt was abandoned since, after treating for 4 days at 100° with phosphorus pentoxide in a high vacuum, a considerable amount of water was still left in the salt. As the crystallized salt is quite hygroscopic, the excess of moisture was removed by placing it in a tube and passing over it a current of air which had previously been passed through 3 ordinary potash bulbs filled with 40 % sulfuric acid, and thereafter filtered. Although the vapor pressure of sulfuric acid at this concentration is considerably above that given for  $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$  at 20°, it was considered advisable to make a determination of the actual magnesium content of the salt. It was found that the salt contained 1.01 % of magnesium in excess of that corresponding to the above formula. This correction has been applied to the calculations.

Anhydrous barium nitrate was also prepared but could not be employed, as it was found to be only slightly soluble in the anhydrous alcohol. Strontium nitrate and strontium and barium chlorides were likewise found to be only slightly soluble, the last named salt being somewhat more soluble than the others.

The alcohol content of the cell was obtained by weighing. Because of the small amount of salt required for the more dilute solutions, these were made up by introducing into the cell a weighed quantity of a more concentrated solution. This solution was weighed in a small pipet, somewhat similar to an Ostwald pycnometer. The outlet tube was protected by means of a cap covering the end of the capillary and the other tube by means of a stopcock. This method of making up the solutions was employed in all cases, except that of calcium nitrate, where the last three concentrations were made by weighing the salt directly. Since the concentration never exceeded 0.1 normal, it was assumed that the density of the solutions is equal to that of the pure solvent, whose density is 0.8043 at 18°.

### III. Experimental Results.

The results are given in the following table, in which the weight  $W$  of the concentrated solution added is given in the first column, the concentration

of the salt in millimols per liter is given in the second column, the molecular conductance  $\Lambda$ , corrected for the specific conductance of the solvent, in the third column, and the logarithm of the dilution  $V$  in the last column. At the head of the table the initial weight of the solvent is given under  $W_0$ , the specific conductance of the pure solvent under  $l_0$ , and the concentration of the added solution under  $C_s$ .

## IV. Discussion of Results.

The results are shown graphically in the accompanying figure, values of  $\log V$  being plotted as abscissas and those of  $\Lambda$ , the molecular conductance, as ordinates. The nature of the electrolyte and the solvent is in each case shown on the figure. In the same figure are shown the conductance curves for sodium iodide, lithium chloride, and calcium chloride, obtained by Schlamp. Since calcium chloride, calcium nitrate, and magnesium nitrate are ternary salts, their molecular conductance, if ionization is anywhere near complete, should be approximately twice that of a binary electrolyte; while, if they ionized according to Equation I, their molecular conductance should be very nearly the same as that of binary electrolytes, the concentration, of course, being expressed in mols per liter.

It is evident from an examination of the curves that Völlmer's conclusion that calcium chloride ionizes according to a binary process is not justified. Schlamp's conductance curve for calcium chloride lies much below that for both lithium chloride and sodium iodide. Moreover, the curve for calcium chloride does not run parallel to that of the curves of the binary salts.

Another uncertainty in Schlamp's results lies in the fact that he has not specified the condition of his calcium chloride. This salt crystallizes as a hexahydrate and is dehydrated with great difficulty. Since he makes no mention of any facts in this connection, it is probable that he employed the hydrated salt. It is also probable that Schlamp's alcohol was not completely free from water, since he dehydrated it only with fused potassium carbonate. The presence of small amounts of water has a great influence upon the conductance curve of electrolytes which exhibit a marked tendency to form compounds containing water of crystallization.

Schlamp's curve for calcium chloride resembles that for the hydrated magnesium nitrate in anhydrous propyl alcohol. The conductance values for the hydrated salts in anhydrous propyl alcohol are relatively low at the

higher concentration and increase markedly at lower concentrations. There is no indication that these curves are approaching a limiting value as

the concentration decreases, and it must therefore be assumed that ions of the type  $\text{M}^{++}$  are present.

No previous data are available on the influence of small additions of water upon the conductance of ternary electrolytes in non-aqueous solutions. In general, the conductance of ternary electrolytes in anhydrous solvents is relatively low. That the ionization is generally increased by the addition of water may be concluded from the work of Jones and his co-workers, who have measured the conductance of a considerable number of mixtures containing 25% of water. It is evident that the initial additions of water cause a large increase in the conductance of the solutions. The addition of 3.62% of water raises the molecular conductance of calcium nitrate from 0.772 to 2.036, or 2.64 times; while the addition of 6.75% raises it to 2.991, or 3.88 times the value in the anhydrous solvent. These

points are represented in the figure by  $\oplus$  at the concentration  $\log V = 1.36$ . A comparison of the conductance curves for magnesium nitrate hexahydrate in dry alcohol and in the presence of approximately 0.7% of water likewise clearly shows the influence of water upon the conductance of the solutions. The two curves intersect at two points. At low concentrations the additions of water cause a marked increase in the conductance of the solution, while at intermediate concentrations the addition of water causes a slight decrease in the conductance of the solution. It is to be presumed that at considerably higher concentrations the addition of water would cause a relatively large increase in the conductance of the solution. It is probable that the curve for anhydrous magnesium nitrate does not differ measurably from that for calcium nitrate. The diminution in the conductance due to the addition of water at intermediate concentrations of salt is probably due to the fact that on addition of larger amounts of water the ionic complexes formed have a relatively lower speed than those which contain less water. Somewhat similar results are obtained on the addition of water to solutions of acids.<sup>5</sup> When small amounts of water are added to solutions of strong acids in alcohol, the equivalent conductance of the acid is greatly reduced. This reduction appears to be due to the formation of a complex hydrogen ion whose speed is relatively low. It is interesting to note that on the addition of water to weak acids the conductance is increased and this increase is in general the greater the weaker the acid. This increase is apparently due to an increase in the ionization of the dissolved electrolyte, due to the addition of water. Lithium chloride in ethyl alcohol also shows a slight increase on addition of water. This influence of water upon the conductance of solutions of electrolytes which show a marked tendency to form complexes with water, is readily accounted for on the assumption that the ionization of the complex formed is greater than that of the non-hydrated electrolyte. This is in excellent agreement with Werner's theory of the constitution of salts.

## V. Summary of Results.

1. The conductance of an anhydrous ternary salt in anhydrous propyl alcohol has been measured.
2. The effect of the addition of varying amounts of water to solutions of anhydrous ternary electrolytes in anhydrous propyl alcohol has been studied.
3. A comparison of the results of the present investigation with those of Schlamp indicates that he employed hydrated calcium chloride.

<sup>5</sup> Goldschmidt, *Z. physik. Chem.*, 89, 129 (1915).

4. A critical examination of the results obtained by Schlamp lends no support to the view that ternary salts in this solvent ionize according to a binary process.

## VAPOR PRESSURE OF LITHIUM NITRATE:AMMONIA SYSTEM.<sup>1</sup>

By R. O. E. DAVIS, L. B. OLMSTEAD AND F. O. LUNDSTRUM.

Received April 4, 1921.

In recent work on the absorption of ammonia from a mixture of hydrogen and nitrogen gases used in ammonia synthesis the desirability of employing as absorbent some substance other than water became evident. A number of good absorbents for ammonia are known, but each has its disadvantages for our purpose. Liquid absorbents seem more desirable than solid but only two other than water which meet most of the requirements have been mentioned in the literature. The desirable qualities in an absorbing liquid are that its water vapor pressure be low over a considerable range in temperature and that the vapor pressure of ammonia vary considerably over a short range in temperature. The liquid should be non-corrosive to ordinary metals so that it can be used as a circulating medium and should not cause any obstruction in the pipes, valves, or other parts of the system.

Solid ammonium nitrate treated with anhydrous ammonia liquefies, giving a liquid rich in ammonia and remaining liquid over considerable range in temperature. This is the well known Divers Solution<sup>2</sup> and has been studied by Kuriloff.<sup>3</sup> Similarly, ammonium thiocyanate forms a liquid with ammonia as first noted by Bradley and Alexander<sup>4</sup> and this has been studied by Foote and Hunter,<sup>5</sup> who have shown some of the desirable properties of this liquid for the purpose we have in mind; namely, the removal of ammonia from a mixture of gases and its subsequent recovery free from these gases. However, a serious draw-back to the use of these liquids is that they attack metals rapidly.

In searching for a suitable liquid absorbent we have investigated substances listed by Franklin and Kraus,<sup>6</sup> as very easily soluble, easily soluble, and miscible in liquid ammonia. A number of these were eliminated as undesirable for our purpose merely by inspection, but quite a number

were tested to determine whether, as with ammonium nitrate, a liquid formed on treatment of the solid with anhydrous ammonia gas. In carrying out these tests 10 g. of the substance was placed in an absorbing bottle and a stream of dried ammonia gas from a liquid ammonia cylinder was passed through the bottle. If evidences of liquefaction were shown after 10 or 15 minutes' treatment this was continued until the entire mass became liquid or no further change was observed in the material. If no change was observed a small amount of water was added and ammonia was passed through again. In some cases small amounts of moisture did cause liquefaction of the mass with high absorption of ammonia. One cc. of the liquid thus obtained was titrated with a standard sulfuric acid solution to determine roughly the amount of ammonia absorbed. The following substances shown in Table I were tested with positive results.

TABLE I.

Of the substances thus tested, lithium nitrate appears to have the highest absorptive value, and hence we have determined the total vapor pressure of seven solutions of lithium nitrate in pure and aqueous ammonia.

These solutions were prepared by saturating c. p. recrystallized lithium nitrate with ammonia at different temperatures. The method used for determining the vapor pressure was a static one, and the apparatus is shown in Fig. 1. The solution was introduced into a bulb connected to a manometer and placed in a thermostat. Stirring

was accomplished by an electromagnetic arrangement consisting of a small plate of sheet platinum attached to a platinum wire carrying on its upper end an iron nail coated

with glass, to prevent corrosion. Movement of the stirrer was accomplished by interrupted current through a solenoid on the outside of the glass tubing just about the height of the upper end of the iron nail. Other features of the apparatus require no special description. Samples of the material used were drawn off through a capillary for analysis for ammonia and for nitrates.

The range of the measurements was from  $-14^{\circ}$  to  $35^{\circ}$ , and the results of these measurements are shown in Fig. 2.

An inspection of the curves shows that lithium nitrate is very soluble in ammonia and that the vapor pressure of the ammonia is very much lowered by the presence of the dissolved salt. The curve is somewhat flatter where water is present and becomes steeper with an increase of ammonia. The curve for lithium nitrate containing no water shows a low vapor pressure of ammonia at  $0^{\circ}$ , and a pressure exceeding an atmosphere at  $35^{\circ}$ , thus giving a rather wide variation of pressure over a comparatively short range in temperature.

## Action on Metals.

Solutions of lithium nitrate in pure and aqueous ammonia were tested as to their action upon certain metals. After remaining in contact with machine steel and iron wire for several months no appreciable action had taken place. Nichrome wire placed in such solutions was not attacked but a nickel-steel alloy showed slight action after many months.

## Use of Solution.

It appears from these results that a solution of lithium nitrate in liquid ammonia with a small addition of water would possess desirable quantities for the removal of ammonia from a mixture of gases such as hydrogen, nitrogen, and ammonia. The absorption could be carried out at a temperature around  $0^\circ$ , or somewhat lower and a large portion of ammonia released either by a comparatively small increase in temperature or by reduction in pressure. The presence of water vapor would not have to be considered if this were an undesirable constituent of the gas leaving the absorbing medium. One of the very desirable properties is that ordinary steel or iron could be used in the construction of apparatus for absorption of ammonia and for circulation of the liquid.

## Summary.

1. A number of substances have been found to liquefy when treated with anhydrous ammonia gas or on the addition of small amounts of water.

2. The total vapor pressures of several mixtures of lithium nitrate, ammonia and water have been measured.

3. The lithium nitrate-ammonia solution could be used as an absorbent for ammonia, as in the synthetic process.

4. The corrosive action of such a solution on ordinary iron or steel is not appreciable after several months' contact.

VAPOR PRESSURE OF AMMONIA-SALT SOLUTIONS.<sup>1</sup>

By R. O. E. DAVIS, L. B. OLMSTEAD AND F. O. LUNDSTRUM.

Received April 4, 1921.

The work leading up to the study of lithium<sup>2</sup> nitrate:ammonia system also led us to consider calcium nitrate; sodium iodide; calcium chloride; ammonia nitrate; and ammonium thiocyanate:ammonia solutions. Ordinary crystalline calcium nitrate with four molecules of water forms a liquid with anhydrous ammonia gas, which is rather viscous at 24°. With the addition of water this solution becomes less viscous and offers the hope of meeting the requirements of an absorbent liquid. The measurements of vapor pressure were carried out in the same apparatus as used in the lithium nitrate experiments. The vapor pressures of two solutions of calcium nitrate, one of which contains 58.34% of water and the other

monia absorbed is somewhat smaller. A solution of calcium nitrate and ammonia seems to possess no special advantages over the lithium nitrate except that of cheapness. However, it does possess one disadvantage, that the presence of carbon dioxide, if by any chance this should get into the gases being scrubbed for removal of ammonia, would cause the

formation of a precipitate which remains in suspension. With continued use this might become objectionable and have to be eliminated from the solution.

Vapor-pressure measurements were made on a calcium chloride-ammonia solution containing 64% of water. While solid calcium chloride absorbs ammonia it does not liquefy, but an absorbent solution is formed with the addition of water. Curve 5 and Table V show the results obtained from measurements with this solution. This shows it to be an absorbent of the same general character as the calcium nitrate but the solution possesses the disadvantage of being corrosive to metals.

Sodium iodide when treated with anhydrous ammonia gas changes to a creamy mass which on the addition of a little water forms a solution with a slight suspension, the character of which was not investigated but is probably due to impurity in the salt. Measurements were made on two solutions, one with 8.2% of water and the other with 51.6% of water. The results of these measurements are seen in Curves 2 and 8 and in Tables II and VII. The solution containing 8.2% of water crystallizes at  $-8^\circ$ .

Both ammonium nitrate and ammonium thiocyanate are substances that liquefy readily with anhydrous ammonia gas. Measurements made on two solutions of these salts are shown in Curves 3 and 4 and Tables III and IV. Curve 7 shows the vapor pressure of 28.15 % of ammonia in water simply for comparison.

### Action on Metals.

Qualitative tests showed that solutions of ammonium nitrate and ammonium thiocyanate in ammonia attacked iron and steel and their alloys with great rapidity. Calcium chloride-ammonia solution was found to be corrosive to a less extent. Solutions of calcium nitrate and sodium iodide did not show immediate action, so that quantitative measurements were made with these solutions.

The results after 3 months showed that no loss occurred from the action of calcium nitrate on machine steel and nickel steel, but ordinary iron was rather badly attacked. Almost identical results were obtained with sodium iodide solutions. While vapor-pressure measurements indicate the possibility of using these solutions for absorbing ammonia from the hydrogen and nitrogen mixture of gases used in ammonia synthesis, it must not be forgotten that the action of hydrogen on halogen compounds or on the thiocyanate might result in introducing into the gas small amounts of halogen or sulfur compounds that would be detrimental to the life of the catalyst. Therefore, of this set of solutions calcium nitrate seems most promising for use as an absorbent for the ammonia.

### Summary.

1. Vapor-pressure curves for solutions of several inorganic salts in ammonia have been constructed.

2. Solutions of ammonium nitrate in ammonia and ammonium thiocyanate are very corrosive to iron and steel; calcium chloride-ammonia is less corrosive, and calcium nitrate-ammonia and sodium iodide-ammonia show no immediate corrosive action.

3. Calcium nitrate-ammonia solutions seem the most promising of these solutions for practical use as an absorbent for ammonia in the synthetic process.

## THE MAGNITUDES OF ATOMS.

BY THEODORE W. RICHARDS.

Received April 12, 1921.

Recently two interesting papers upon the diameters of atoms have been published, namely, those of W. L. Bragg<sup>1</sup> and A. Landé.<sup>2</sup> The former makes use of the method of X-ray reflection; whereas the latter depends upon Bohr's theory. In view of the fact that the results do not agree, it may be not uninteresting to point out that another much simpler and less recondite method of obtaining approximate estimates of diameters of some of the atoms in question under varying circumstances has been available for several years. This method, although it is probably no more uncertain than either of the methods mentioned above does not seem to have attracted general attention.

In a paper<sup>3</sup> summing conclusions concerning atomic volumes, I pointed out that from the study of the contractions which occur when elements combine together with the compressibilities of those elements, it is possible to draw a plausible inference as to the bulk which the elements occupy when combined. A graph (which had as its main object the proof that the magnitude of the contraction is dependent in part upon the magnitude of the compressibility of the factors) was given, depicting the compressibilities of the metals of the alkalis compared with the contraction occurring during the formation of their chlorides. This graph is represented in the uppermost curve of the accompanying diagram (Fig. 1) which now gives also corresponding curves for bromides and iodides.

"An interesting corollary suggested by this diagram is to be found in the extrapolation of the curve toward the left. The point where the abscissa becomes zero indicates the hypothetical contraction which would take place if an imaginary incompressible element were combined with chlorine by an affinity about equal to that of the others, to form a compound similar to lithium chloride." Since, in this case, the contraction of 12.5 cc. must be due to the 25.1 cc. of chlorine alone, we may suppose that in each of the actual cases of the alkali chlorides the contraction must be about the same, and that in each case the chlorine occupies about  $25.1 - 12.5 = 12.6$  cc. From this assumption and the actual total contractions, the hypothetical bulk which each atom must oc-

<sup>3</sup> T. W. Richards, *THIS JOURNAL*, 36, 2417 (1914).

cupy in its chloride was computed. The numerical estimates are based, as has been said, upon the assumption that the chlorine is equally compressed by the several affinities of the alkali metals. The assumption is partially justified by the fact that the heats of formation of the sev-

Fig. 1.

Fig. 1.—Graphs depicting the compressibilities of the alkali metals compared with the contraction during the formation of their halides. Contraction on combination in cc. per mol is plotted ordinately; compressibilities of the elements are plotted as abscissas.

eral chlorides are nearly the same, and by the further fact that in such cases heat of formation is not very different from free energy change. Because the possible error of a cubic centimeter or two would make very little difference in the atomic diameters, however, these values will nevertheless be adequate for the present purpose.<sup>4</sup> The probability is, that the affinity of the alkali metal increases somewhat as the atomic weight increases, which would make the volume of the chlorine somewhat less than 12.6 cc., especially in the cases of the heavier metals. Hence the values given below for the metals are minimal values.

<sup>4</sup>There is no need at present of attempting the analysis of the other questions which might affect such an estimate. In this latter category comes the question as to how nearly free energy change (which means the work which may be done in excess of that involved in the atomic compression) represents the force of affinity, and also the question as to the effect of the differing atomic volumes of the metals, which involve at the same time different bulks to be compressed and different surfaces exposed to pressure—circumstances partially counterbalancing one another. The heats of formation of the 5 alkali chlorides are respectively 392, 399, 431, 462, and 479 kilojoules.

On comparing the result for chlorides with those for bromides and iodides, it becomes evident that whereas the extrapolated value for the contraction of chlorides in forming alkali chlorides is about 12.6 cc., that of bromine on forming the alkali bromides is only about 8 cc. and that of iodine only about 2 cc. These latter figures (which likewise represent minimal values) are reasonable, since bromine in the elementary state is undoubtedly already much more compressed than chlorine. The so-called "atomic volumes" of bromine and iodine being respectively 25.6 and 25.7 cc., the bulks which these elements occupy in the bromides and iodides of the alkali metals can hardly exceed 17.6 and 23.7 cc. per gram atom respectively. Subtracting these values from the well-known molecular volumes of the halides we obtain the following values for the bulk of the metals in these compounds. As already said, all the figures for the metals being minimal values should probably be increased somewhat with increasing molecular weights; hence the table gives conservative evidence which can hardly fail to avoid exaggerating the differences to be emphasized.

TABLE I.—ATOMIC VOLUMES OF HALOGENS AND ALKALI METALS IN COMBINATION.  
(Cc. per gram Atom.<sup>a</sup>)

	In chlorides.	In bromides.	In iodides.
Halogen.....	12.60	17.60	23.70
Lithium.....	7.90	7.47	9.26
Sodium.....	14.45	14.53	17.21
Potassium.....	24.92	25.70	29.46
Rubidium.....	30.61	31.77	36.12
Cesium.....	29.74	30.39	33.90

\* The second decimal place is not significant with regard to the individual values, but is significant with regard to their sums, which are simply the "molecular volumes" of the salts. The densities (20°/4°) used in these calculations were as follows: for the 5 alkali metals, respectively, 0.534; 0.9712; 0.8621; 1.532; and 1.882; for the 3 halogens, respectively 1.412; 3.120; and 4.94; for the 5 chlorides respectively, 2.068; 2.161; 1.987; 2.798; and 3.974; for the 5 bromides respectively, 3.464; 3.203; 2.749; 3.349; and 4.433; for the 5 iodides respectively 4.061; 3.665; 3.123; 3.550; and 4.509. See T. W. Richards and F. N. Brink, *THIS JOURNAL*, 29, 117 (1907); G. P. Baxter, *Am. Chem. J.*, 31, 558 (1904); Baxter and Wallace, *THIS JOURNAL*, 38, 265 (1916). If Dewar's lower value for iodine were taken, the values for the bulk of the metals in the iodides would be somewhat reduced, but would still be much larger than the bulk in the bromides. (*Chem. News*, 91, 216 (1905)). The compressibilities recorded in Fig. 1 are those of Richards and Stull, *Carnegie Inst. Pub.*, 7 (1903), and 76 (1907).

This table is striking in its evidence (wholly consistent except in the case of lithium bromide), that the metals are in a less compressed state in the bromides than in the chlorides and in a still less compressed state in the iodides. Such an outcome is only reasonable, considering the undoubted difference in the affinities of the halogens for the alkali metals, and granting that affinity and cohesion produce pressure and are

thus capable of diminishing the volume of the atoms and molecules upon which they act.

That this method gives reasonable and consistent results is shown by a similar calculation involving the three halides of potassium. These, evolving respectively 431, 398 and 335 kilojoules in their formation show attendant volume changes of respectively —33.0, —27.7 and —18.0 cc. Extrapolating to zero compressibility both sets of values (plotted as above in relation to the compressibility of the halogen) to represent an imaginary incompressible halogen, we find that the heat of the formation of the imaginary halide of potassium would be 300 kj. and the attendant contraction (to be referred wholly to the potassium) about 14 cc. per mol. Assuming direct proportionality,<sup>5</sup> the 431 kj. evolved when potassium chloride is formed should then correspond to about 20 cc. contraction of the potassium. We have seen that the contraction of the chlorine is to be considered as about 12.6. The sum of these two values 32.6, is very near the actual contraction, 33.0. Hence we may reasonably believe that the contraction has been rightly apportioned between the two component elements, and therefore that the volumes of the combined atoms are known with rather surprising exactness.

The figures in the table just given record the so-called "atomic volumes" of the metals in the several halides. From these figures, thanks to the remarkable investigations of Millikan and Perrin and others, we are able to compute at once the bulks occupied by the individual atoms and therefore the diameters which they must possess. Assuming that each gram-atom contains  $6.062 \times 10^{23}$  atoms, the following table is obtained for the bulk of the individual atoms in question under the varying circumstances.

TABLE II.—VOLUMES OF INDIVIDUAL ATOMS UNDER VARYING CIRCUMSTANCES.

Each Value is Multiplied by One Septillion ( $10^{24}$ ) cc.

	In chlorides.	In bromides.	In iodides.
Halogen.....	20.8	29.0	39.1
Lithium.....	13.0	12.3	15.3
Sodium.....	24.3	24.4	28.4
Potassium.....	41.1	42.4	48.6
Rubidium.....	50.5	52.4	59.6
Cesium.....	49.0	50.1	55.9

Since in the halides, on account of the large volume changes and the intensity of compression, the atoms of the elements must be compressed

<sup>5</sup> The true relationship is doubtless not one of exact proportionality, but in the absence of knowledge as to its nature this may be assumed as a first approximation. Of course a similar correction should be applied to the halogens as given in the table, each of which must really have different values in combination with the different metals. Here, however, the affinities concerned being more nearly equal for any given halogen, this correction seemed to be a work of supererogation.

into nearly cubical form<sup>6</sup> (See Fig. 2), a close approximation to the distance between the faces of the atoms is to be obtained by simply tak-

Fig. 2.

ing the cube roots of the volumes. This approximate distance in the case of chlorine is  $20.6 \times 10^{-24} = 2.75 \times 10^{-8}$  cm. The following table records the results.

TABLE III.—THE CUBE ROOTS OF THE VOLUMES OF INDIVIDUAL ATOMS UNDER VARYING CIRCUMSTANCES.

(Each Value expressed in Ångstrom units.)

	In chlorides.	In bromides.	In iodides.
Chlorine.....	2.75	....	....
Bromine.....	....	3.09	....
Iodine.....	....	....	3.39
Lithium.....	2.35	2.35	2.48
Sodium.....	2.90	2.90	3.05
Potassium.....	3.45	3.49	3.65
Rubidium.....	3.70	3.74	3.91
Cesium.....	3.66	3.69	3.82

A clearer insight into the meaning of these figures may be gained from a glance at the diagram, which, representing the arrangement in space of the atoms of the alkali halides, has since been essentially confirmed by W. H. and W. L. Bragg, and may be considered as fairly certain.<sup>7</sup> Incidentally attention may be called to the fact that the crystal must be built up of quadrimolecular units of this sort, not units with 3 atoms on each edge, since the latter unit (having 27 atoms in all) would have a surplus of one atom either of chlorine or metal.<sup>8</sup> Whether or not such cubes unite evenly so as to cause the crystal to be a single molecule does not greatly concern us at present.

<sup>6</sup> T. W. Richards, *THIS JOURNAL*, 35, 381 (1913); 36, 1686 (1914).

<sup>7</sup> Compare W. J. Sollas, *Proc. Roy. Soc.*, 63, 273 (1898), who first proposed this arrangement, without, however, postulating atomic compression. See also T. W. Richards, *THIS JOURNAL*, 35, 381 (1913).

<sup>8</sup> Compare W. H. and W. L. Bragg, "X-rays and Crystal Structure," 1916, p. 95.

A glance at the diagram shows that the data as given above in Table III need a slight correction, since they are computed for perfect cubes, and the "atomic domain" of the larger atom of her pita must have its cubic shape somewhat modified in order to attain perfect close packing. In other words, because of the basis of the calculation, it is necessary to account for *all* the molecular volume. This fact must cause the true distance between the atomic centers to be slightly greater than half the sum of any two of these cube roots—unless the two atomic volumes are identical, when half the sum of the roots gives the exact value. The true distance between the atomic centers may obviously be found by calculating the edge of the cube or crystal unit depicted in Fig. 2. Such a cube involves 4 molecules. The gram-molecular volume of CsCl is 42.34; hence of 4 CsCl, 169.36 cc. Dividing by  $6.062 \times 10^{23}$  and extracting the cube root of the result we have  $6.53 \times 10^{-8}$  cm., the exactly computed length of the edge of such a cube. The sum of the atomic diameters given in Table III is 6.40, a difference of 0.13 Ångstrom. This difference must be due to the modification of the larger of the two cubes at the inside edges, as shown in the diagram. Only in the cases of rubidium chloride and lithium iodide is any other deviation as great as this. Usually the effect is negligible.

Evidently, since the smaller cube of any pair is probably not essentially modified, its value may be taken as correctly given in the preceding table, and the distance between the faces of the larger atom may be computed as the difference between the total value and the smaller exact cube root from Table III. These distances may be called "atomic diameters" of which the corrected values are given in the table below, compared with the figures for the same elements obtained by Landé and Bragg respectively.

TABLE IV.—DIAMETERS ( $d$  OR  $d'$ ) OF INDIVIDUAL ATOMS OF ALKALI METALS AND HALOGENS (IN ÅNGSTROM UNITS).

	Landé.	Bragg.	T. W. R. In chlorides.	T. W. R. In bromides.	T. W. R. In iodides.
Chlorine.....	3.3	2.1	2.8	...	...
Bromine.....	3.6	2.4	...	3.1	...
Iodine.....	4.1	2.8	...	...	3.4
Lithium.....	...	3.0	2.3	2.4	2.6
Sodium.....	2.2	3.5	2.9	2.9	3.1
Potassium.....	2.9	4.2	3.5	3.5	3.7
Rubidium.....	...	4.5	3.8	3.8	3.9
Cesium.....	3.2	4.7	3.8	3.7	3.8

It is striking that the newly recorded values all lie about half way between those of Landé and those of Bragg. Landé's results for the halogens are all much larger, and accordingly, his results for the metals all much smaller than the other estimates. One cannot help thinking that

Landé's estimates are in error, especially because his value for iodine, for example, corresponds with an "atomic volume" of this element in iodides of 38.8 cc., which means an *expansion* per 127 g. of iodine of over 13 cc. in the act of forming an iodide. All evidence upon the question of volume change in chemical reaction contradicts such a conclusion. Nevertheless it is interesting that Landé's figures, depending upon hypothetical assumptions, should be as close to the others as they are.

Bragg's results, depending much more closely upon experiment, are safer, but seem to demand a rather excessive contraction of halogen. For example, a gram-atom of chlorine in the act of combination, is made to contract from 25.1 cc. to 5.6 cc., which seems unlikely. Probably the method of calculation (which involved no consideration of the changing volume of an atom under varying affinity-pressures) must have caused this anomaly. While admitting that the atom (or its "sphere of influence") might change somewhat in size, he does not appear to have correlated different values in relation to the affinities concerned.

Bragg's statement<sup>9</sup> that the cesium atom, when combined with a halogen, occupies less space than the rubidium atom, is verified by these new results. He points out that with oxygen compounds of cesium the reverse is the case. May not the reason for this apparent contradiction be simply that the affinity of cesium for the halogens is much greater than the affinity of cesium for oxygen? The heat of oxidation of a gram-atom of cesium is only 172 kj., whereas  $\text{Cs} + \text{Cl}$  evolves 479 kj. In the case of a very compressible element like cesium this difference of affinity is quite enough to account for the apparent contradiction, and all the results fall thus into line.

The importance of change of volume under the influence of chemical affinity and cohesion, in any such calculations, cannot be over-estimated. The arguments in favor of it, based upon the comparative volumes of liquids and solids, are so convincing as to leave no doubt concerning the magnitude of the changes involved.<sup>10</sup> They are not matters of theory, but the actual result of the comparison of accurately determined molecular volumes of elements and compounds. For example, 70.6 cc. of cesium combines with 25.1 cc. of liquid chlorine (95.7 cc. in all) to make only 42.34 cc. of cesium chloride. That such contractions are greater the greater the compressibilities of the elements concerned, is likewise clear, and so is the effect of the cohesion of the product.

The fact that the "atomic domain," or "sphere of influence," or "atomic playroom," or "practical bulk of the atom," (as this space has been variously called) thus changes, makes the assignment of any fixed volume to it under varying conditions illusory. The only reason why definite

<sup>9</sup> W. L. Bragg, *Phil. Mag.*, [6] 40, 174 (1920).

<sup>10</sup> T. W. Richards, *THIS JOURNAL*, 36, 2417 (1914).

bulks could be assigned as a first approximation to chlorine, bromine and iodine in the last three columns of Table III, is because the affinities of any one of these halogens for the different alkali metals are so nearly alike that the extent of chemical and cohesive compression of any one halogen must be nearly the same when in combination with each of the five metals. But even here this assumption cannot be absolutely correct although it serves as the basis of a conservative first approximation. Correction for this error would bring new results somewhat nearer to Bragg's, but apparently could not, in any probability, give volumes of the metallic atoms as large as he makes them.<sup>11</sup>

There is nothing, in the present paper, inconsistent with the brilliant experimental results of the Professors Bragg. The only premise needed for the construction of a completely consistent scheme from all these varied data seems to be the recognition of the almost certainly ascertained conclusion that affinity and cohesion are capable of altering the "atomic domain," and that the compressibilities of the factors affect the outcome. Taking all these considerations together it is evident that there has been attained an insight into the actual magnitudes of the space demanded by atoms in crystals which was not dreamed possible twenty years ago.

The bearing of these conclusions upon the "valency volume" hypothesis of Pope and Barlow may be noted, but needs no discussion.<sup>12</sup>

### Summary.

In brief it is pointed out that the contraction suffered during combination, taken in connection with the compressibilities of the elements combined, makes possible an approximate estimate of the bulk occupied by the several constituents in a compound.

Calculations are made for the diameters of the atoms of the halogen and the alkali metals, which diameters are found to lie about half-way between the results of Bragg and those of Landé.

Emphasis is placed upon the importance of considering the compressing effect of the affinities concerned, in making any comparison of atomic volume.

CAMBRIDGE 38, MASS.

<sup>11</sup> In a careful calculation (too complicated to be worth printing in this brief notice) in which maximum allowance was made for all reasonable corrections to these results, only one of them (CsI) was changed more than 0.1 Ångström. In this one case the "atomic volume" of the combined iodine found was only 19 cc. instead of 23.7, which makes the atomic diameter of this element 3.15 instead of 3.39 Ångström. This corrected value would make the diameter of the Cs atom 4.09 instead of 3.85. Most of the values given above were practically unchanged by this calculation.

## THE ENTROPY OF ELECTRON GAS.

BY RICHARD C. TOLMAN.

Received April 21, 1921.

## 1. Introduction.

It has become increasingly evident that physical chemists can achieve considerable simplification in mode of expression and thought by treating electrons as the atoms of a chemical substance. Just as we speak of the substance chloride ion and write for it the formula  $\text{Cl}^-$ , we may speak of the substance electron and write for it the formula  $\text{E}^-$ , and the use of such symbols in electrochemistry has already become usual.

In the case of the electrons given off from a heated filament we may properly speak of the substance electron gas. Richardson<sup>2</sup> and his co-workers have indeed shown that these electrons are actually emitted with velocities which are distributed in the different directions in accordance with Maxwell's distribution law for the molecules of a gas which cross any plane boundary. Whatever the distribution of emitting velocities may be, however, if we had an evacuated vessel with walls made from the filament substance and raised the walls to a high temperature, the vessel would fill with electron gas which would exert a definite vapor pressure, depending on the temperature of the walls. Laue<sup>3</sup> has recently made an elaborate investigation of the conditions under which this gas will obey the perfect gas laws, while the application of thermodynamic reasoning to the behavior of the gas has been made familiar by the work of H. A. Wilson,<sup>4</sup> Richardson<sup>2</sup> and others.

Owing to the very considerable force of repulsion between electrons, the conditions under which this gas will not deviate appreciably in behavior from a perfect monatomic gas are more stringent than for most monatomic substances, which usually have a moderate attraction between molecules rather than a strong repulsion. In order for electron gas to obey the perfect gas laws, the concentration must be low enough and the temperature high enough so that the effects produced by the repulsive force between the electrons can be neglected in comparison with effects produced by their thermal agitation. Furthermore, on account of the mutual repulsion of the electrons, the dimensions of the containing vessel must be small unless we are willing to allow a higher concentration at the periphery than in the center of the gas. And finally the containing walls

<sup>1</sup> Published by permission of the Chief of Ordnance.

<sup>2</sup> Richardson, "The Emission of Electricity from Hot Bodies," Longmans, Green and Co., London, 1916.

<sup>3</sup> Laue, *Ann. Physik.*, **58**, 695 (1919).

<sup>4</sup> H. A. Wilson, *Phil. Trans.*, **202A**, 258 (1903).

must all be of the same material and at the same temperature since otherwise the Volta effect will set up differences in electric potential between different portions of the vessel which will destroy the uniform concentration of the gas.

It should be noted that these restrictions which are necessary in order that the perfect gas laws may apply are of the same nature and merely more stringent than those encountered in the case of more familiar gases. All gases obey the perfect gas laws more closely as their concentration is made lower and their temperature higher. Furthermore in large masses of gas the gravitational attraction of the gas for itself leads to an increased concentration at the center analogous to the increased concentration at the periphery in the case of electron gas. Finally the local disturbances in concentration which would be produced by differences in potential between different parts of the containing walls are entirely analogous to the differences in concentration which may be produced in ordinary gases by the gravitational effect of external bodies.

Perhaps the most distinguishing characteristic of electron gas is that it is apparently a gas which is *plus que parfait* at all temperatures and pressures while most gases are *moins que parfait* throughout the greater range of temperature and pressure. It should also be pointed out that the mechanism by which electron gas exerts its pressure is obviously not that of the older kinetic theories which assumed a bombardment of the walls by rigid elastic molecules. This consideration, however, need cause us no concern, since we have already learned even in the case of more familiar gases to regard the above mechanism at least as no better than a first approximation. In the case of any gas dilute enough the exact nature of the mechanism by which the momentum is transferred to the walls has no effect on the final value of the pressure.

## II. Theoretical Equation for the Entropy of Electron Gas.

Assuming now that we have electron gas under such conditions that it obeys the laws for a perfect monatomic gas law we may evidently write for its entropy per mol,

$$S = 5/2 R \ln T - R \ln p + \text{const.} \quad (1)$$

With regard to the constant occurring in Equation 1, Laue<sup>5</sup> has already made the suggestion that this constant will depend on molecular weight in the same way as has been found for other monatomic gases. If this be true, we may rewrite Equation 1 in the form

$$S = 5/2 R \ln T - R \ln p + 3/2 R \ln M + S_1 \quad (2)$$

where  $M$  is the molecular weight of the electron and  $S_1$  has the same value for all monatomic gases

<sup>5</sup> Laue, *Jahr. Radioakt. Elektronik*, 15, 257 (1918).

In a recent article<sup>6</sup> the author has shown the possibility of deriving Equation 2 in a very simple way from the principle of similitude or relativity of size, and has found that the entropy of a number of monatomic gases at 25° is closely given by Equation 2 when  $S_1$  is given the value 24.27,<sup>7</sup>  $S$  and  $R$  being in calories per degree,  $T$  in degrees centigrade absolute,  $p$  in dynes per sq. cm. and  $M$  the molecular weight in grams.

The main purpose of the present article is to show that the entropy of electron gas as calculated from Equation 2 actually agrees with the entropy of the electron gas in equilibrium with tungsten, tantalum and molybdenum filaments at 2000° absolute as calculated from the heat known to be absorbed when electrons are emitted from the hot filaments. Having thus assured ourselves of the probable validity of Equation 2, we shall then make use of this equation in a following article to study the thermal ionization of gaseous vapors at high temperatures.

**Pressure of Electron Gas in Equilibrium with Hot Filaments.**—In order to apply Equation 2 to the electron gas in equilibrium with hot filaments, we must evidently have a value for the pressure of the gas in equilibrium with the filament. Now there is a well-known relation between the pressure of a gas  $p$ , and the number of mols of gas  $N$  which cross a plane surface of unit area in unit time. This relation may be written in the form,

$$N = \frac{p}{\sqrt{2\pi M R T}} \quad (3)$$

and can be simply derived merely from the assumption that the velocities of the molecules are distributed in accordance with Maxwell's distribution law.

In the case of a filament in equilibrium with an electron gas, Equation 3 will determine the number of electrons impinging on unit area of the filament in unit time. Since we have equilibrium the number impinging

<sup>6</sup> Tolman, *THIS JOURNAL*, 42, 1185 (1920).

<sup>7</sup> In the article referred to, it was shown that the entropy of a number of monatomic gases at 298° K and one atmosphere pressure could be calculated from the formula,

$$S = \frac{3}{2} R \ln M + 25.1 \text{ calories per degree per mol.}$$

Comparing with Equation 2, it is evident that we may write,

$$\frac{5}{2} R \ln T - R \ln p + S_1 = 25.1$$

Putting  $R = 1.985$  calories per degree,  $T = 298^\circ \text{K}$ ,  $p = 1,013,200$  dynes per sq. cm., and solving for  $S_1$  we obtain the value 24.27.

Some of the methods for deriving Equation 2 based on the quantum theory lead to a theoretical value for  $S_1$ . Nevertheless a complete agreement as to this theoretical value does not yet seem to have been achieved. For this reason it has seemed to the present writer desirable to use the experimental value.

on the filament surface must be equal to the number leaving the surface, and this latter will be equal to the number reflected by the surface plus the number freshly emitted by the surface. If  $r$  is the fraction of the impinging electrons which are reflected and  $i$  is the saturation current per unit area which can be obtained when all the electrons emitted by the surface are removed as fast as formed, and we assume that the emission of electrons from the hot filament takes place in the same way under equilibrium conditions as when the saturation current is being measured, we may write as an expression for the equality of the number of electrons impinging on the surface and leaving the surface per unit time,

$$N = r N + \frac{i}{F} \quad (4)$$

where  $F$  is the Faraday (*i. e.*, the quantity of electric charge carried by one mol of electrons). Substituting the value of  $N$  given by Equation 3 and solving for the pressure  $p$ , we obtain,

$$p = \frac{i \sqrt{2 \pi M R T}}{F (1-r)} \quad (5)$$

In order to use this equation for the case of the electrons in equilibrium with hot filaments we shall use Langmuir's<sup>8</sup> careful measurements of the saturation currents for tungsten, tantalum and molybdenum filaments at 2000° K, as given in the second column of Table I. For  $M$ , the molecular weight of the electron we shall take  $5.44 \times 10^{-4}$  g., for  $R$ ,  $8.315 \times 10^{-7}$  ergs per degree per mol, for  $T$ , 2000° K, and for  $F$ , 96540 coulombs.

As to the value for  $r$  for the fraction of the electrons reflected we have very meager data. Richardson<sup>9</sup> estimates that about 30% of the slow moving electrons present in the absence of an electric field are reflected from a brass surface. Gehrts<sup>10</sup> found 42% reflection for aluminum, 58% for lead, 52% for cobalt, 56% for copper and 10% for lamp-black surfaces with electrons which had been emitted from a copper plate by the action of ultra-violet light and then accelerated by a drop of potential of 2 volts. When no voltage drop was applied the percentage reflection was less in those cases where measurements were actually made, but there is some uncertainty as to the exact interpretation of the results owing to the possible disturbing effect of gas molecules left in the evacuated tube.

Fortunately very exact information as to  $r$  is not necessary, since it will be seen from an examination of Equations 2 and 5 that it enters into the final expression for entropy as an additive term of the form,

$$R \ln(1-r).$$

<sup>8</sup> Langmuir, *Trans. Electrochem. Soc.*, 29, 125 (1916).

<sup>9</sup> Richardson, *loc. cit.*, p. 155.

<sup>10</sup> Gehrts, *Ann. Physik.*, 36, 995 (1911).

If  $r$  has the value zero this term has the value zero. If  $r$  should have a value as great as 0.5, the whole term would only have the value of 1.4 entropy units in a total which is going to be about 50 entropy units. Under the circumstances we shall neglect the reflection altogether and put  $r = 0$ .

Substituting the above numerical values into Equation 5 we have obtained values for the pressures of the electron gas in equilibrium with the filaments, as given in the third column of Table I. It will be seen that the pressures of the electron gases in equilibrium with these filaments are so exceedingly low as to give us confidence in our assumption that the gas laws are valid.

TABLE I.

Filament.	$i_{2000^\circ}$ .	$\frac{\text{amperes}}{\text{sq. cm.}}$	$p \frac{\text{dynes}}{\text{sq. cm.}}$	$S_{2000^\circ}$ .
Tungsten.....	0.0042		$1.037 \times 10^{-8}$	53.3
Tantalum.....	0.007		$1.729 \times 10^{-8}$	52.3
Molybdenum.....	0.013		$3.210 \times 10^{-8}$	51.0

**Numerical Values of Entropy from Equation 2.**—We are now ready to substitute into the theoretical Equation 2. Expressing entropy in calories per degree we shall take  $R = 1.985$  calories per degree,  $T = 2000^\circ \text{ K}$ ,  $M = 5.44 \times 10^{-4}$  grams, and  $S_1 = 24.27$ . Substituting these values together with the pressures just determined into Equation 2 we have obtained the values for the entropy of the electron gases given in the fourth column of Table I.

### III. Calculation of the Entropy of Electron Gases from Heat of Vaporization.

It has long been realized from the work of Richardson, that the emission of electrons from a hot filament is accompanied by an absorption of heat. This was made evident in the first place by the great temperature coefficient for the thermal emission of electrons. More recently, however, Richardson<sup>2</sup> has actually shown and measured the cooling of a filament when a given number of electrons are allowed to escape and the inverse effect of heating when the electrons are absorbed. Fairly exact measurements of the cooling effect have more recently been made by Lester.<sup>11</sup>

If  $\Delta H$  is the heat absorbed when a mol of electrons is reversibly evaporated at temperature  $T$ , it is evident that the increase in entropy of the system will be given by the equation,

$$\Delta S = \frac{\Delta H}{T}. \quad (6)$$

<sup>11</sup> Lester, *Phil. Mag.*, 31, 197 (1916).

This increase in entropy is obviously equal to the entropy  $S$  of the electron gas which has been formed plus the change in the entropy of the metal  $\Delta S_m$  which occurs when one mol of electrons is removed, so that we may rewrite Equation 6 in the form,

$$S = \frac{\Delta H}{T} - \Delta S_m. \quad (7)$$

The quantity  $\Delta S_m$  which is the change in the entropy of a large quantity of metal when one mol of electrons is removed is presumably small, since owing to the small mass of electrons and the strong constraints under which they are held within the metal they are known from specific heat data to pick up thermal energy only very slowly as the temperature is raised above the absolute zero. For example, in the case of tungsten, the specific heat at room temperature ( $300^\circ \text{K}$ ) is known to have about the theoretical value  $C_v = 6.0$ , predicted on the assumption that the electrons have acquired no thermal energy. At  $2000^\circ \text{K}$  Worthing<sup>12</sup> finds  $C_v = 7.0$ . If we assumed that the partial specific heat of the electrons over the whole range from  $300^\circ \text{K}$  to  $2000^\circ \text{K}$  were the whole difference between these figures or one calorie per degree, the partial entropy acquired by all the electrons in one mol of tungsten at  $2000^\circ$  would only be 1.9 entropy units. Under the circumstances we shall feel justified in neglecting the change in the entropy of the metals in question when the electrons are evaporated and shall write directly,

$$S = \frac{\Delta H}{T} \quad (8)$$

where  $S$  is the entropy of the electron gas, the same quantity which we have already calculated from the theoretical Equation 2.

**The Heat of Vaporization of Electron Gas.**—In order to carry out the calculations indicated by Equation 8, we shall make use of the direct determinations of Lester<sup>11</sup> of the heat lost by a filament when electrons are evaporated from it. These measurements were made by comparing the change in the resistance of a filament produced by the cooling effect of electron emission with the change in resistance produced by a known change in the current used for heating the filament.

Lester has calculated his results on the assumption that the electrons leaving the hot filament have the kinetic energy  $2RT$  per mol which, in accordance with Maxwell's distribution law is the average kinetic energy of the molecules of a gas which cross any plane boundary in a given time interval. Since the experimental results of Richardson<sup>13</sup> and his co-workers have actually demonstrated that the velocities of the electrons emitted from a hot filament are distributed in accordance with the Max-

<sup>12</sup> Worthing, *Phys. Rev.*, 12, 199 (1918).

<sup>13</sup> Richardson, *op. cit.*, p. 139 and following.

well law, we may accept this assumption. Lester's calculations also assume that the electrons in the metallic part of the circuit bring with them into the hot filament the energy  $2RT_c$  where  $T_c$  is the temperature of the cool part of the circuit. This latter assumption is presumably not an exact approximation of the truth. Nevertheless the whole correction term,  $2R(T - T_c)$ , is only a few per cent. of the total heat effect so that our lack of exact information is not serious.

Lester's results may be expressed with the help of the equation,

$$P = F\phi + 2R(T - T_c) \quad (9)$$

where  $P$  is the actual energy input per second which Lester found was necessary in order to produce the same numerical change in filament temperature as was produced by the evaporation of one mol of electrons per second;  $F$  is the Faraday or quantity of electricity carried by one mol of electrons,  $\phi$  is the equivalent potential drop which the electrons have to overcome in escaping through the surface of the metal and the correction term  $2R(T - T_c)$  has the significance already discussed.

For  $\phi$  Lester gives the values in volts shown in the second column of Table II. If we multiply  $\phi$  by  $F = 96540$  coulombs, we find the energy input in joules necessary to take one mol of electrons across the boundary of the metal, under the conditions of the experiment and shall assume this same energy input necessary for a reversible evaporation. In order to get the reversible heat of vaporization we must add to the energy input the quantity  $RT$  which is the external work that would have to be done against a movable piston if one mol of electrons were reversibly evaporated. We obtain for the heat of vaporization,<sup>14</sup>

Taking  $T = 2000^\circ \text{K}$  and expressing  $\Delta H$  in calories, the values obtained are given in the third column of Table II. Substituting in Equation 8

<sup>14</sup> It should be noted that this expression for  $\Delta H$  is based on Lester's assumption that the electrons in a metal at temperature  $T$  have the same mean kinetic energy as the molecules of a perfect gas at the same temperature, which does not agree with the low specific heat of metals already referred to above in connection with our estimate of  $\Delta S_m$ .

If we assumed that the electrons in the metal had no kinetic energy, we could then get  $\Delta H$  as follows. Take Lester's value of  $P$ , subtract  $2RT$  which is the kinetic energy of the escaping electrons when the saturation current is being measured, add  $\frac{3}{2}RT$  which would be the kinetic energy of the electrons in the space surrounding the filament of electrons under equilibrium conditions and add  $RT$  for the external work. We should obtain

$$\Delta H = P - 2RT + \frac{3}{2}RT + RT$$

or substituting Lester's expression for  $P$

$$\Delta H = F\phi + \frac{3}{2}RT - 2RT_c$$

Since  $T_c$  was actually a little less than  $T$ , it will be seen that expression used above for  $\Delta H$  was not greatly different from that which would be calculated by this other method.

$$\Delta H = F\phi + RT.$$

we obtain the values given in the fourth column of Table II for the entropy of one mol of electron gas in equilibrium with tungsten, tantalum and molybdenum filaments at 2000° K. For comparison the values calculated by the theoretical Equation 2 are given in the last column of the table.

TABLE II.

#### IV. Discussion.

**The Data Selected.**—The three filaments considered, namely, tungsten, tantalum and molybdenum are the only ones for which both Langmuir has given values of the saturation current and Lester values of the heat of vaporization. Values for the heat of vaporization  $\Delta H$  might also have been obtained by making use of the Clausius vapor-pressure equation,

$$\frac{d \ln p}{dT} = \frac{\Delta H}{RT^2}$$

by substituting the value for pressure  $p$  in terms of saturation current  $i$  given by Equation 5,

$$p = \frac{i \sqrt{2\pi M RT}}{F(1-r)}$$

This would permit us to extend our considerations to any filament for which we have accurate values of the saturation current and the rate of change of saturation current with the temperatures. The comparisons seemed more conclusive, however, if we restricted ourselves to the case, of heats of vaporization which have been directly determined. Moreover it should be noted that in using the indirect method of determining heats of vaporization, we should have to introduce the additional assumption that  $dr/dT$  as well as  $r$  is a negligible quantity. Furthermore, the data on the rate of change of saturation current with temperature are usually expressed with the help of Richardson's original formula  $i = aT^{3/2} e^{b/T}$  where  $a$  and  $b$  are constants, and since this formula has no completely satisfactory theoretical justification, we might be led into error if we made use of it over a wider range of temperature than that in which it is empirically reasonably valid.<sup>15</sup>

<sup>15</sup> Making use of Langmuir's data (*loc. cit.*,) for the rate of change of saturation current with the temperature, and calculating  $\frac{\Delta H}{T}$  by the method described above, the

following results have been obtained for the entropy of electron gas in equilibrium with

**The Agreement.**—The agreement between the values for the entropy of electron gas as given by the theoretical Equation 2 and as calculated from the known heats of vaporization agree very well as shown in the last two columns of Table II. It is believed that the results may be taken as an adequate proof that the entropy of a dilute electron gas may be calculated from the same theoretical equation as has been found to apply to other monatomic gases. Of course, an exact agreement between the two methods of calculation is hardly to be expected, first because of experimental error in the data employed and secondly because of a number of assumptions which had to be introduced in the course of the calculations in order to arrive at any conclusions at all.

**The Assumptions.**—A recapitulation and discussion of these assumptions will not be out of place.

(a) In order to obtain Equation 5 for the relation between saturation current and the pressure of the electron gas in equilibrium with a hot filament, it was assumed that the same number of electrons will be given off per second by a hot filament, when electron gas is in equilibrium with the filament and when the saturation current is being determined. A partial justification for this assumption is provided by the fact that the current is found to be independent of the anode potential as soon as a high enough voltage drop has been applied to overcome the backing up effect of the space charge. With the Coolidge X-ray tube this has been shown to be true even at voltages above 100,000 volts.<sup>16</sup> Under the circumstances, we may conclude that the electron emission will not be decreased by the small-potential drop in the opposite direction present under equilibrium conditions.

To complete the justification for our assumption that the electron emission is the same under equilibrium conditions when the saturation current is being determined, we also need assurance that under equilibrium conditions no secondary emission is produced by electrons which bombard the emitting walls, since such a bombardment is not present when the saturation current is being determined. This seems to be justified in view of the work of Gehrts, already referred to, which shows that a potential drop of about 11 volts is necessary to produce secondary emission in the case of surfaces of aluminum, lead, cobalt and copper, and this for hot filaments at 2000° K. The values given in the last column are those obtained from the theoretical Equation 2 by the method already described.

Filament.	$S = \frac{\Delta H}{T}$ .	$S$ theoretical.
Tungsten .....	54.1	53.3
Tantalum .....	51.6	52.3
Molybdenum .....	51.6	51.0
Thorium .....	40.7	31.1

<sup>16</sup> Coolidge, *Phys. Rev.*, 2, 409 (1913).

sponds to a much higher kinetic energy than that of the average molecule at 2000°.

(b) In making actual calculations of the pressure with the help of Equation 5 it was assumed that the reflecting power of the hot metals in question is zero. This is probably not strictly true, in view of the work of Gehrts<sup>10</sup> on the reflecting power of a number of cold metallic surfaces. Nevertheless the effect of possible condensed layers of gas might increase the reflecting power of cold surfaces such as those with which he worked. Moreover, as already pointed out, a reflecting power anywhere between 0 and 50% would have but little effect on the final value of the entropy.

(c) In calculating the entropy of electron gas from its heat of vaporization, we have assumed that the values of Lester for the heat of vaporization when the vaporized electrons are being removed as fast as emitted is the same as the heat of vaporization under equilibrium conditions. This assumption is obviously closely connected with assumption (a) that the emission of electrons takes place to the same extent under equilibrium conditions and when the saturation current is being determined. Since assumption (a) occurred in the first method of calculating entropy and assumption (c) in the second method of calculation, the errors introduced, if any, may have cancelled out.

(d) In calculating the entropy of electron gas from its heat of vaporization, we have also neglected the change in the entropy of a metal produced by a change in its electric charge. This assumption is probably not strictly correct. The electrons in a metal, however, are held by strong constraints and have a small mass and hence pick up appreciable amounts of thermal energy only at high temperatures where, in accordance with the fundamental equation  $dS = dQ/T$  the rate of increase in entropy compared with the rate of increase in heat content is small.

**Conclusion.**—It is believed that this article establishes with reasonable certainty the possibility of calculating the entropy of electron gas from the theoretical equation which has been found to apply to other monatomic gases, namely,

$$S = \frac{5}{2} R \ln T - R \ln p + \frac{5}{2} R \ln M + S_1$$

where  $S_1$  has the same value for all monatomic gases.

UNIVERSITY COLLEGE OF WALES.]

## LANGMUIR'S THEORY OF THE ARRANGEMENT OF ELECTRONS IN ATOMS AND MOLECULES.

BY CHARLES R. BURY.

Received April 28, 1921.

Langmuir<sup>1</sup> pictures an atom as consisting of a positively charged nucleus and electrons, equal in number to the units of positive electricity with which the nucleus is charged (or the atomic number of the element), which are arranged in concentric spherical shells of equal thickness round the nucleus. The electrons, though free to rotate or oscillate about their mean positions, are definitely localized in the atom. They are situated in cells, all of equal volume in any given atom: since there are 2 cells in the inner shell, there will be 8 in the second, 18 in the third and 32 in the fourth.

In his fourth postulate, Langmuir states that each cell can contain two electrons, except the two cells in the inner shell, which can contain only one: and that there can be no electrons in the outer shell until all the inner shells contain their maximum numbers of electrons.

By substituting an alternative to this fourth postulate it is possible to get a series of atomic structures similar to those obtained by Langmuir for the elements of lower atomic weight than sodium, but different for those of higher atomic weight. These structures are preferred by the author for the following reasons: (1) they give a better explanation of the chemical properties of the elements; (2) the necessity of postulating cells "independent of the electrons in them" is avoided. At the same time, the inconsistency that some cells can contain two electrons, others only one, is also avoided. The alternative postulate is as follows. The maximum number of electrons in each shell or layer is proportional to the area of its surface; thus, successive layers can contain 2, 8, 18 and 32 electrons. Groups of 8 and 18 electrons in a layer are stable, even when that layer can contain a larger number of electrons. The maximum number of electrons in the outer layer of an atom is 8: more than 8 electrons can exist in a shell only when there is an accumulation of electrons in an outer layer. During the change of an inner layer from a stable group of 8 to one of 18, or from 18 to 32, there occurs a transition series of elements which can have more than one structure.

**The Two Short Periods.**—This postulate will leave unaltered the structures assigned by Langmuir to the elements of the first short period.

Sodium will have 2 electrons in the inner layer, 8 in the second, and one in the third; an arrangement that can conveniently be abbreviated as

<sup>1</sup> Langmuir, *THIS JOURNAL*, 41, 868 (1919).

(2,8,1). The succeeding elements in the second short period will each have one more electron in the third layer, up to argon with the structure (2,8,8), its chemical properties being attributed to the stability of the group of 8, not to the outer layer being complete, for the third layer can contain 18 electrons. For the structure of the elements of this period, Langmuir doubles the electrons in the cells of the second layer. The proposed alteration of structure suggests no difference in chemical properties from those deduced by Langmuir.

**The First Long period.**—Since 8 is the maximum number of electrons in the outer layer, potassium, calcium and scandium must form a fourth layer, although their third is not complete. Their structures will be (2,8,8,1), (2,8,8,2) and (2,8,8,3).

The elements from titanium to copper form a transition series, in which the stable but incomplete group of 8 in the third layer is changed to a saturated group of 18. With the accumulation of 4 electrons in the fourth layer of titanium, there is the possibility of some of them passing into the third unsaturated layer. These transition elements can have more than one structure, and the following are possible structures that the elements assume in their various compounds.

Ti	(2,8,8,4)	(2,8,9,3)	(2,8,10,2)		
V	(2,8,8,5)	(2,8,9,4)	(2,8,10,3)	(2,8,11,2)	
Cr	(2,8,8,6)	(2,8,11,3)	(2,8,12,2)		
Mn	(2,8,8,7)	(2,8,9,6)	(2,8,11,4)	(2,8,12,3)	(2,8,13,2)
Fe	(2,8,10,6)	(2,8,12,4)	(2,8,13,3)	(2,8,14,2)	
Co	(2,8,13,4)	(2,8,14,3)	(2,8,15,2)		
Ni	(2,8,14,4)	(2,8,15,3)	(2,8,16,2)		
Cu	(2,8,17,2)	(2,8,18,1)			

Of course, many more possibilities might be predicted. The question why only stable compounds corresponding with some of the possibilities exist and why unstable compounds correspond with others, while some possibilities are not represented in any known compounds, can be only partly answered. An accumulation of 4 electrons in the outer layer suffices in favorable circumstances to send one of them into the inner layer, but the tendency for one out of a group of 3 electrons to pass into the inner layer will be much less, while the tendency for 2 electrons to force one of themselves into the inner layer will be very small. This accounts for the great instability of the divalent salts of titanium, vanadium and chromium, in which they will have the structures (2,8,10,2), (2,8,11,2) and (2,8,12,2). Only one element, copper, forms a series of monovalent salts, in which it will have the structure (2,8,18,1), this structure being made possible by the stable group of 18 in the third layer. On the other hand, once several electrons have been forced into the third layer, the group of 8 is destroyed, and further electrons do not meet with the same resistance in passing into the third layer. Finally, in cobalt, nickel

and copper, the stable group of 8 in the third layer is impossible: such a structure would involve more than 8 electrons in the fourth, or the formation of a fifth layer. Electrons meet with little resistance in passing into the inner layer: the elements have no tendency to form compounds in which they exhibit a high valence, and their divalent salts are found to be the most stable.

The octet theory of valence in its plain straightforward form applies to the compounds of these elements: and this method of treatment compares favorably for practical convenience and simplicity with the elaborate arrangement of electrons in molecules which Langmuir's structures demand for the elements, while at the same time it affords a satisfactory explanation of their chemical properties. Thus manganese, in the permanganates, has the structure (2,8,8,7), and differs from chlorine (2,8,7), in its kernel only, just as chlorine differs from bromine, but not in the outer layer of electrons, on which the valence and type of compound depend. In chromates, manganates and ferrates, the metals have the structure (2,8,8,6), (2,8,9,6) and (2,8,10,6), having the same outer layer as sulfur (2,8,6) or selenium (2,8,18,6), but their kernels resemble each other far more than they resemble the kernels of sulfur or selenium; consequently, while they resemble sulfates and selenates, they resemble each other more closely. If Langmuir's structures for these elements are accepted, they should show no more resemblance than such series as carbon dioxide, nitrogen peroxide and ozone, or silica, phosphorus tetroxide, sulfur dioxide and chlorine peroxide. In the manganites, ferrites and in the dioxides of manganese, iron, cobalt, and nickel, the metals have 4 electrons in their outer layers. In their trivalent salts which all the transition elements except copper form, they have three electrons in their outer layers; and in their divalent salts, which they all form, they have only two. Throughout this transition series of elements, similar compounds are attributed to the elements having a similar outer layer of electrons, and differing only in their kernels.

It seems impossible to give a rational explanation of the chemical properties of such an element as manganese unless the possibility of more than one structure is postulated. Langmuir is driven to inconsistency in attempting to ascribe a structure to sodium manganate. Its chemical properties demand that the manganese atom should form an octet, but there is one electron too many. According to Langmuir's postulates there is no room for it in the inner layers; he has to invent a fresh position for electrons in the atom; the extra electron is held prisoner between the kernel and the octet which the manganese atom holds in common with the 4 oxygen atoms. If the structure of manganese is regarded as invariable, divalent salts, such as manganous chloride, present even greater difficulties. Such a compound would be formed by one electron passing

from the outer layer of the manganese atom to each of the two chlorine atoms, leaving 5 free electrons in the outer shell of the manganese atom. No octet is formed round the manganese atom in which these 5 could be held prisoner. Free electrons in the outer shell of an atom cause a substance containing that atom to be highly reactive, yet manganous salts are probably the most stable compounds of manganese.

Lewis<sup>2</sup> in his hypothesis of the cubical atom expresses the opinion that in these elements "the kernel of the atom is not uniquely and permanently defined." In his magneton theory of the structure of the atom, Parson<sup>3</sup> uses the conception of "tautomerism" in the structure of the atom to account for the structure of the elements of the first long period.

The remaining elements of this period have their 3 inner shells complete. Zinc will have the structure (2,8,18,2): there is no possibility of change of structure, and it is therefore a normal element and resembles magnesium and glucinum, the two normal elements of lower atomic weight that have two electrons in the outer layer. Each succeeding element in the period will have one more electron in the fourth shell. Krypton will have the structure (2,8,18,8) and, like argon, owes its chemical properties to the stability of the group of 8 in the outer layer, although this fourth layer is unsaturated, for it can hold 32 electrons.

**The Second Long Period.**—The chemical properties of this group seem to indicate that the groups of 8 and 18 electrons in the fourth layer are more stable than they were in the third.

Rubidium (2,8,18,8,1), strontium (2,8,18,8,2), and yttrium (2,8,18,8,3) are analogous to potassium, calcium and scandium. A fifth layer is being built over an incomplete fourth shell.

The electrons in the outer layers of zirconium, columbium and molybdenum show little tendency to pass into the inner layers. Their chemical properties, so far as they are known, seem to be explained by one structure only for each element, (2,8,18,8,4), (2,8,18,8,5) and (2,8,18,8,6), respectively. In this they differ from the elements preceding them in their respective groups, titanium, vanadium and chromium. Those compounds in which they exhibit their highest valence are relatively more numerous, and in these alone do they resemble the elements of the first long period. The divalent salts of molybdenum, which are probably complexes of more elaborate constitution than their simple empirical formulas would suggest, are very different from the divalent salts of the transition elements of the first long period. Molybdates have not the same oxidizing properties that the chromates have.

No element of atomic number 43, corresponding to manganese, has as yet been discovered.

<sup>2</sup> Lewis, *THIS JOURNAL*, 38, 785 (1916).

<sup>3</sup> Parson, *Smithsonian Misc. Coll.*, 65, No. 11, p. 23 (1915).

The fact that ruthenium forms a tetroxide, in which it must have the structure (2,8,18,8,8), shows that in this period the electrons pass into the inner layer less readily than in the first long period, for iron shows no sign of having a similar structure.

Again, possibly owing to the greater stability of the group of 18 electrons in the fourth shell, silver forms only monovalent salts, in which it must have the structure (2,8,18,18,1); unlike copper, it shows no tendency to form divalent salts in which it would have the structure (2,8,18,17,2). This causes the process of transition from a group of 8 to one of 18 electrons in the fourth shell to be much shorter, and to be more sudden than it was in the third shell. In the first long period, there were 8 transition elements; in the second long period there are only 3, ruthenium, rhodium and palladium; and these show but little resemblance to their analogs in the first long period, iron, cobalt and nickel. As transition elements, they may have different structures in their different compounds, and the following possibilities can be recognized:

Ru (2,8,18,8,8) (2,8,18,9,7) (2,8,18,10,6) (2,8,18,12,4) (2,8,18,13,3) (2,8,18,14,2)  
 Rh (2,8,18,11,6) (2,8,18,13,4) (2,8,18,14,3) (2,8,18,15,2)  
 Pd (2,8,18,14,4) (2,8,18,15,3) (2,8,18,16,2)

As in the previous transition series in the first long period, the lower valences of the first transition elements lead to the formation of unstable compounds; ruthenium and rhodium divalent salts are unstable. The last transition element, palladium, shows the same preference for the lower valences that is characteristic of cobalt and nickel; palladium trioxide and its derivatives are unknown, and palladium alone, of this series, forms stable divalent salts. In this transition series, it is a rule, not without exceptions, that those structures that contain an even number of electrons in the fourth shell lead to the formation of the most stable compounds.

Silver has the structure (2,8,18,18,1): the fourth shell is still incomplete, for it can contain 32 electrons. It nevertheless contains a stable group of 18. This stable but incomplete group of 18 electrons in the fourth shell remains to the end of the second long period, each succeeding element having one more electron in the fifth layer. It is possible that such compounds as cadmous oxide ( $\text{Cd}_2\text{O}$ ), indium dichloride, and the stannous salts might be ascribed to electrons passing from the fifth to the incomplete fourth layer, but no such possibility can account for the existence of gallium and germanium dichlorides. The last elements of this period form compounds by completing the octet in the fifth layer; and the transition from 18 to 32 electrons in the fourth shell does not occur till the next period.

Xenon will have the structure (2,8,18,18,8).

**The Rare Earth Period.**—Cesium, barium and lanthanum will have the structures (2,8,18,18,8,1), (2,8,18,18,8,2) and (2,8,18,18,8,3) respectively, a sixth layer being built over incomplete but stable groups of 18 and 8 electrons in the fourth and fifth shells.

Periodic arrangement of the elements and structure of their atoms. No attempt to represent the variable structures of the four transition series has been made.

Cerium is the first of a transition series in which the group of 18 electrons in the fourth layer is changed to one of 32. In previous transition series, succeeding elements have differed in similar compounds only by one electron in the outer shell of their kernels: in this series they will differ only by one electron in an inner shell, the fourth, of their kernels. The elements will therefore resemble each other in similar compounds even more closely than, for example, manganese, iron, cobalt, nickel and copper in their divalent salts. A second feature of this transition series is that the elements do not show that variety of structure that is found in other transition series, though a few elements show signs of having more than one structure. The following structures are suggested.

Ce	(2,8,18,18,8,4)	(2,8,18,19,8,3)
Pr	(2,8,18,19,8,4)	(2,8,18,20,8,3)
Nd	(2,8,18,21,8,3)	
Undiscovered element of atomic number 61.		(2,8,18,22,8,3)
Sa	(2,8,18,23,8,3)	(2,8,18,24,8,2)
Eu	(2,8,18,24,8,3)	(2,8,18,25,8,2)
Gd	(2,8,18,25,8,3)	

So far as their chemical properties are known, the remaining seven rare earths show no sign of having more than one structure. Each succeeding element will have one more electron in the fourth shell. Lutecium, the rare earth of highest atomic weight, will have the structure (2,8,18,32,8,3); the fourth shell is now complete, and it will be a normal element. Lutecium, rather than lanthanum (2,8,18,18,8,3), resembles scandium (2,8,8,3) and yttrium (2,8,18,8,3), just as, in the first long period, zinc rather than calcium resembles glucinum and magnesium.

Between lutecium and tantalum an element of atomic number 72 is to be expected. This would have the structure (2,8,18,32,8,4), and would resemble zirconium.

Tantalum and tungsten have the structures (2,8,18,32,8,5) and (2,8,18,32,8,6), and are analogous to columbium and molybdenum. An element of atomic number 75 remains undiscovered.

Osmium, iridium, platinum and possibly gold form a transition series in which the group of 8 in the fifth layer changes to a group of 18 electrons. This third 8-18 transition resembles the second, rather than the first, such transition; and in fact, osmium, iridium, and platinum, resemble ruthenium, rhodium and palladium more than they resemble iron, cobalt and nickel. The various structures which these elements, as transition elements, can assume are probably as follows.

Os (2,8,18,32,8,8) (2,8,18,32,10,6) (2,8,18,32,12,4) (2,8,18,32,13,3) (2,8,18,32,14,2)  
 Ir (2,8,18,32,11,6) (2,8,18,32,13,4) (2,8,18,32,14,3) (2,8,18,32,15,2)  
 Pt (2,8,18,32,12,6) (2,8,18,32,14,4) (2,8,18,32,15,3) (2,8,18,32,16,2)  
 Au (2,8,18,32,16,3) (2,8,18,32,17,2) (2,8,18,32,18,1)

In this transition series also, the first elements have a tendency to form compounds with the highest valences, and the last elements to form compounds with the lower valences. Those compounds in which the metal has an even number of electrons in its fifth shell are generally more stable than when the number of electrons in the fifth layer is odd.

Mercury will have the structure (2,8,18,32,18,2), the 4 inner shells being complete, the fifth containing an incomplete but stable group of 18 electrons. Each succeeding element in this period will have one more electron in the sixth layer, until we come to niton, with the structure (2,8,18,32,18,8).

**The Last Period.**—Only 5 elements of this period are known, and the chemical properties of only two of them, thorium and uranium, are known well. In this period a second 18-32 transition series may be expected.

The second 8-18 transition series was shorter and more sudden than the first, possibly because of the greater stability of the groups of 8 and 18 electrons in the fourth, than in the third shells; and the elements of the second transition series showed but little resemblance to those of the first. To judge by analogy, the second 18-32 transition series may be expected to begin later, to end earlier, to be shorter and more abrupt than the first 18-32 transition series. Little resemblance between the chemical properties of the elements of the two series is to be expected. Possibly an element, not yet discovered, of atomic number 94, two more than that of uranium, is the first of a series of 7 transition elements that would be metals, something like the ruthenium group but more electropositive. Possibly uranium itself is the first member of this second 18-32 transition

series. The following structures are suggested for the elements of this period.

Ra	(2,8,18,32,18,8,2)	Th	(2,8,18,32,18,8,4)
Ac	(2,8,18,32,18,8,3)	Ux <sub>2</sub>	(2,8,18,32,18,8,5)
	U	(2,8,18,32,18,8,6)	

The structures for the elements arrived at are more in harmony with the atomic diameters, determined by Bragg<sup>4</sup> from the study of crystal structure, than are the structures given by Langmuir.

Element.	Atomic diameter in Å. (Bragg).	Number of shells in kernel. (Langmuir). (Bury).	
Lithium.....	3.00	1	1
Sodium.....	3.55	2	2
Potassium.....	4.15	2	3
Rubidium.....	4.50	3	4
Cesium.....	4.75	3	5
		Number of shells in atom.	
Fluorine.....	1.35	2	2
Chlorine.....	2.10	2	3
Bromine.....	2.38	3	4
Iodine.....	2.80	3	5

On the basis of Langmuir's structures for the elements, the difference in atomic diameter between rubidium and potassium might be expected to be more than that between potassium and sodium, for both the latter contain 2 shells of electrons, while rubidium contains 3. On the basis of the atomic structures suggested in this paper, the difference in atomic diameters between any two successive elements in the same group might be expected to be constant.

During the course of preparation of this paper, structures similar to those suggested by the author for the inert gases have been proposed by Bohr,<sup>5</sup> who bases his arguments on the study of emission spectra.

### Summary.

An alternative to Langmuir's fourth postulate, in his paper on the arrangement of electrons in atoms and molecules, has been suggested. This avoids the necessity of postulating cells in the structure of the atom, and leads to different structures for the elements of higher atomic weight than neon. It is claimed that the application of Lewis and Langmuir's octet theory of valence to these structures gives a better explanation of the chemical properties of the higher elements, than can be obtained from Langmuir's structures.

THE VOLUMETRIC DETERMINATION OF SULFIDE BY  
OXIDATION TO SULFATE.

BY H. H. WILLARD AND W. E. CAKE.

Received April 28, 1921.

In the usual iodometric oxidation of hydrogen sulfide to sulfur only two equivalents of oxygen are required, whereas if it is oxidized to sulfuric acid, eight equivalents are necessary. It would obviously be a distinct advantage to use the latter process instead of the former, if it could be as readily accomplished. Of the methods suggested for this purpose only three can be considered as reasonably accurate. Feit and Kubierschky<sup>1</sup> added to the sulfide excess of standard bromate solution, acidified with sulfuric acid, boiled off the bromine liberated in the reaction and titrated the excess of bromate iodometrically. Dean<sup>2</sup> oxidized hydrogen sulfide with a large excess of standard iodate solution in a solution containing sufficient hydrochloric acid to form iodine chloride and titrated the excess with standard *iodide* solution. Kolthoff<sup>3</sup> added an excess of standard bromine solution and determined the excess iodometrically. The first and last methods have several obvious disadvantages and the second one requires a high concentration of hydrochloric acid, which is somewhat inconvenient, since alkaline solutions must be used to absorb hydrogen sulfide. In connection with the use of hypobromite in the determination of ammonia<sup>4</sup> it seemed desirable to investigate the use of this reagent (and also hypochlorite) for the oxidation of sulfide to sulfate. It was found that if the solution is sufficiently alkaline the oxidation goes very rapidly according to the equation,  $4 \text{NaBrO} + \text{Na}_2\text{S} = 4 \text{NaBr} + \text{Na}_2\text{SO}_4$ . The excess of hypobromite is easily determined by adding potassium iodide, acidifying, and titrating the liberated iodine by means of thio-sulfate. The same reaction occurs with hypochlorite, but less readily.

## Preparation of the Standard Hypobromite Solution.

A solution of convenient concentration was prepared by adding 100 g. of bromine slowly and with constant stirring to a solution of 60 g. of pure sodium hydroxide in 1600 cc. of water, keeping the solution well cooled. Such a solution is about 0.6 *N* and 1 cc. corresponds to approximately 2.4 mg. of sulfur. Since the presence of traces of iron, copper and other metals increases enormously the rate of decomposition of the solution, it is advisable to let the hydroxide solution stand for a day or two and filter or siphon off the clear liquid, before adding the bromine. It should be kept in the dark; but even with pure materials the rate of decomposition is appreciable.<sup>4</sup> Fleury<sup>5</sup> has shown that this

<sup>1</sup> Feit and Kubierschky, *Chem. Ztg.*, **15**, 351 (1891).

<sup>2</sup> Dean, *THIS JOURNAL*, **40**, 619 (1918).

<sup>3</sup> Kolthoff, *Pharm. Weekblad*, **56**, 143 (1919).

<sup>4</sup> Willard and Cake, *THIS JOURNAL*, **42**, 2646 (1920).

<sup>5</sup> Fleury, *Compt. rend.*, **171**, 957 (1920).

may be greatly decreased by adding to each liter of solution 1 g. of potassium iodide or iodate. This suggestion was tried, with contradictory results. One solution changed rapidly to bromide and bromate, the total oxygen remaining unchanged. Another, more dilute in hypobromite but containing relatively more alkali, showed almost no change. The reason for this difference in behavior is being investigated.

#### Preparation of the Standard Hypochlorite Solution.

A hypochlorite solution made from sodium hydroxide purified as described above is much more stable. It was prepared by passing into a cold solution of 90 g. of sodium hydroxide in 1500 cc. of water sufficient dry chlorine to give an increase in weight of about 35 g. Table I shows the rate of change of this solution when kept in the dark at about 22°.

TABLE I.

Date.	Cc. of 0.1 <i>N</i> thiosulfate sol. equivalent to 10 cc. of hypochlorite sol.
Nov. 7	69.16
8	69.06
12	68.96
26	68.67
Dec. 3	68.34
8	68.18
25	67.57

#### Procedure.

In the experiments described the procedure was as follows. To the alkaline sulfide solution was added sufficient standard hypobromite or hypochlorite solution so that not over two-thirds of it was reduced by the sulfide. After standing for 3 to 5 minutes, 2 to 3 g. of potassium iodide was added and the solution diluted to 4 or 5 times the original volume. The solution was neutralized with conc. hydrochloric acid (the color of the iodine acts as an indicator) and 3 to 5 cc. in excess was added. The iodine was then titrated with standard thiosulfate solution.

#### Effect of Varying the Concentration of Sodium Hydroxide.

Unless a certain minimum concentration of sodium hydroxide is present the oxidation is incomplete. This is shown in Table II. To 50 cc. of sodium hydroxide solution of the concentration given were added 5 cc. of standard sodium sulfide solution and 10 cc. of standard hypobromite or hypochlorite solution; the excess was titrated as described above. The theoretical value as determined by an iodine titration is 9.86 cc.

TABLE II.

Conc. of NaOH solution. <i>N</i> .	Cc. of NaClO reduced.	Cc. of NaBrO reduced.
1	7.05	8.11
2	9.45	9.50
3	9.68	9.82
4	9.73	9.82
5	9.83	9.86
6	9.85	9.86

It was found, using 2 *N* sodium hydroxide solution, that, in the case of hypochlorite, heating to 45° for 5 minutes reduced the error a little, but standing for 30 minutes at room temperature had no effect. From this it is evident that, when using hypobromite, the concentration of sodium hydroxide during the reaction must be at least 2.5 *N* and when using hypochlorite, 4 *N*. Practically, therefore, only hypobromite would be used, but experiments were made with both reagents.

The first experiments were made with a solution of sodium sulfide prepared by absorbing about 2 g. of hydrogen sulfide in 16 g. of sodium hydroxide dissolved in a liter of water. Ten cc. of this solution was pipetted into a flask, 10 cc. of 10 *N* sodium hydroxide solution added, then 20 cc. of standard hypobromite solution. After standing for 5 minutes 100 cc. of water was added and 3 g. of potassium iodide. The solution was acidified with conc. hydrochloric acid, 5 cc. in excess being added. The iodine was titrated with thiosulfate. The results are shown in Table III.

This method was found to be rapid and accurate for the determination of sulfur in steel. The steel was dissolved in hydrochloric acid in the usual way, the hydrogen sulfide absorbed in sodium hydroxide and titrated as described above. The other gases, such as hydrocarbons and phosphine, either were not absorbed or did not reduce the oxidizing solution.

#### Procedure for Steels.

Weigh out 5 g. of the steel into a 250-cc. flask through which hydrogen can be passed and which is connected with a "10-bulb tube" for absorbing the hydrogen sulfide. Flush out the apparatus with hydrogen and run into the flask 100 cc. of hydrochloric acid (sp. gr. 1.1). After the reaction has moderated heat the solution just to boiling for 5 minutes after the steel

has dissolved, while passing hydrogen through the apparatus. The solution in the absorption tube should contain about 6 or 7 g. of sodium hydroxide in a volume of 50 to 60 cc. With as little water as possible wash the contents of the bulbs into a flask containing 10 cc. of 0.3 *N* hypobromite solution, let stand for 3 to 4 minutes, add 2 to 3 g. of potassium iodide in solution, dilute to 150 cc., add conc. hydrochloric acid till neutral, and then 5 cc. more. Titrate the iodine with 0.1 *N* thiosulfate solution. If hypochlorite is used more sodium hydroxide must be added.

**Precautions.**—If the solution is not sufficiently alkaline, oxidation will be incomplete.

The solution when neutralized must be kept cool enough to avoid volatilization of iodine.

Low results will be obtained unless the apparatus is flushed out with hydrogen.

Table V shows the results obtained by this procedure. 10 cc. of hypobromite solution was used in all determinations except those marked with an asterisk, in which hypochlorite was used.

### Procedure for Sulfides.

If the sulfide is soluble in hydrochloric acid, no preliminary treatment is required. Insoluble sulfides are first ignited with powdered iron (reduced by hydrogen) free from sulfur, in an atmosphere of hydrogen or carbon dioxide, the ferrous sulfide<sup>6</sup> thus formed being soluble in acids. The sample is treated in the same way as described for steels, except that 0.6 *N* hypobromite and 0.2 *N* thiosulfate solutions are more convenient, and the volume of the former must be increased according to the amount of sulfide present. Table VI shows the results obtained with samples of zinc and cadmium sulfides and mixtures of the two. Hypochlorite was used in Expts. 3 and 4. In Expts. 11 and 12 the sulfide was first

<sup>6</sup> Zehetmayer, *Z. angew. Chem.*, 23, 1359 (1910).

ignited with powdered iron, and the slightly higher value obtained is due to reduction of a small amount of sulfate which was present.

The method may be applied to the direct oxidation of precipitated sulfides, but not natural sulfides. Zinc, mercuric and antimony sulfides were found to react readily with hypobromite and probably all others would do so. If free sulfur or polysulfide is also present, as is often the case, this too will be oxidized, although it has no effect in the iodine method.

It should be emphasized that all other reducing agents, ammonia for example, must be absent, since many substances not oxidized by iodine are oxidized by hypobromite.

#### Summary.

1. Sulfide is rapidly and completely oxidized to sulfate by excess of hypobromite in a solution 2.5 *N* with sodium hydroxide or by hypochlorite in a 4 *N* solution. The excess of oxidizing agent is determined iodometrically. Four times as much oxygen is required as in the usual titration with iodine.

2. The method gives accurate results in the determination of sulfur in steels and in sulfides, if care is taken to exclude all other reducing agents.

## ADSORPTION OF RADIUM BY BARIUM SULFATE.

BY FRANK E. E. GERMANN.

Received May 2, 1921.

The study of the laws of adsorption is usually restricted to those substances which adsorb appreciable masses of material. It is on this account that charcoal is used to such a large extent. The reason for this limitation is that our analytical methods cannot be used to detect the difference in concentration of a solution caused by adsorbents that are not very active. As a result, our knowledge of adsorption phenomena is restricted to a rather limited region.

The case of the adsorption of a radio-active substance by a solid is an exception to the usual type, as in this case we have methods of measurement available other than the usual analytical methods. In the case of the emanation method of the analysis of the radium content of a solution, it is a simple matter to obtain an accuracy of 2 to 5%, where the total radium content is much less than one part per billion.

If radium-free barium sulfate be added to a standard solution of radium barium chloride, a certain quantity of the radium will be adsorbed by the sulfate. After equilibrium has been established, the sulfate can be filtered off and the residual radium in the solution determined. We thus have an ideal method for the study of the laws of adsorption which is applicable to the adsorption of masses which lie far below the quantities which could be determined analytically. The accuracy of the method is all that could be desired.

The study of this particular case is of considerable importance in the commercial refining of radium. Commercial hydrochloric acid contains appreciable quantities of soluble sulfates, which must be precipitated by means of barium chloride before the acid is used to dissolve the carbonates carrying the radium. If the barium sulfate is allowed to settle and the clear acid decanted as used, it may happen at times that traces of the insoluble sulfate are carried over with the acid. The question then arises as to the possible harm that this could do in the extraction of the radium from the carbonate. If the acid-insoluble "tails" run high in radium, how much of this should be attributed to the presence of barium sulfate? It was with these problems in view that the following investigation was undertaken.

A solution of radium barium chloride in approximately *N* hydrochloric acid was made up, and, after standing for several days, was standardized, as far as the radium content was concerned, by means of 3 samples, sealed for a month. When the emanation had reached equilibrium, it was boiled off in the usual way and the radium content of the solution determined.

The average of these 3 determinations showed a radium content of  $22.79 \times 10^{-10}$  g. of radium per cc. of solution.

The barium sulfate was prepared by adding sulfuric acid to a dilute solution of pure barium chloride while boiling. Prepared under these conditions, the sulfate settled readily, and could easily be washed by decantation to rid the precipitate of the sulfuric acid. The barium sulfate was then filtered off, dried, and ignited in a muffle for several hours to remove any residual traces of acid. After cooling, it was pulverized in an agate mortar and passed through a 200-mesh sieve in order to have greater uniformity in the size of the particles.

Ten cc. of the standard radium solution was then diluted to 80 cc. and 0.05 g. of barium sulfate added. The mixture was then boiled for about 20 hours, under a reflux condenser. Experience showed that equilibrium is not reached in 10 hours, but that boiling longer than 18 hours produced no further change in the mass adsorbed. After the adsorption equilibrium had been established, the barium sulfate was filtered off and the solution sealed and set away for a month prior to the emanation determination. Similar runs were made on the same volume of standard solution with varying masses of barium sulfate. Making all the runs under similar conditions, the final volumes of the solutions at equilibrium were the same, and hence the conditions were comparable. The results are tabulated below. Ten cc. of standard solution was used in all experiments.

Expt.	BaSO <sub>4</sub> G.	Ra/cc. at equil. $\times 10^{10}$ G.
1	0	21.86
2	0	23.62
3	0	22.89
4	0.05	18.55
5	0.10	15.08
6	0.10	15.15
7	0.20	8.45
8	0.20	10.48
9	0.30	5.86
10	0.40	3.97
11	0.50	2.70

In addition to the above experiments, one blank was made up with all of the reagents except the standard radium solution. No activity was obtained from this test run, which served as a guarantee that the substances used were all free from radium with the exception of the standard radium solution.

According to the experimental work of Kroeker<sup>1</sup> on adsorption, we may write

$$\left( dx = \lambda \frac{a-x}{v} dm \right) \quad (1)$$

<sup>1</sup> Kroeker, Thesis, Berlin, 1892.

where  $x$  represents the mass adsorbed,  $a$  the total mass initially dissolved,  $v$  the volume of the solution,  $m$  the mass of the adsorbent, and  $\lambda$  a constant. On integrating the above expression, we obtain the equation

$$\lambda = v/m \ln \left( \frac{a}{a-x} \right) \quad (2)$$

Since  $x$  represents the mass adsorbed,  $(a-x)$  would represent the concentration of the solution after adsorption equilibrium had been established, provided the volume  $v$  be taken as unity. Under these conditions, let  $(a-x)$  be designated by  $y$ . Our equation becomes

$$\begin{aligned} \lambda &= 1/m \ln a/y \text{ or} \\ \ln y &= -m \lambda + \ln a \end{aligned} \quad (3)$$

which, written in the exponential form would be

$$y = a e^{-m\lambda} \quad (4)$$

According to Equation 3 it is evident that any case of true adsorption would give us a straight line curve if we plot  $\log y$  as ordinates against mass  $m$  as abscissas. Curve I shows this to be the case.

Fig. 1.

If we admit with Freundlich<sup>2</sup> that

$$\lambda = v/m \ln \frac{a}{a-x} = \alpha \left( \frac{a}{s} \right)^{-1/n} \quad (5)$$

in which  $\alpha$  and  $n$  are constants depending only on the temperature and the nature of the dissolved substance, it can be shown that the usual form of the adsorption isotherm

$$x/m = \beta c^{1/p} = \beta \left( \frac{a-x}{s} \right)^{1/p} \quad (6)$$

<sup>2</sup> Freundlich, *Z. physik. Chem.*, 57, 395 (1906).

can be derived from 5 by expanding the two sides of the equation in series and neglecting all but the first term of each series. The term  $c$  is the concentration of the solution at equilibrium. Writing Equation 6 in the logarithm form, we obtain

$$\ln x/m = 1/p \ln c + \ln \beta \quad (7)$$

which shows that if we plot the logarithms of the ratio of the mass adsorbed to the adsorbing mass ( $\log^* x/m$ ) against the logarithm of the equilibrium concentration, we should have a straight line. Curve II shows that this is borne out by experiment.

Fig. 2.

The usual procedure in adsorption work has been to use some such substance as blood charcoal, which adsorbs large quantities of material. Thus, in one set of experiments due to Freundlich, acetic acid and blood charcoal being used, the concentration of acid varied from 0.02 to 2.80  $N$ , while the mass adsorbed per gram of charcoal varied between 0.028 and 0.226 g. In the experiments recorded in the present article, we are dealing with altogether different orders of magnitude. The concentration of radium chloride adsorbed per gram of adsorbent ( $\text{BaSO}_4$ ) was of the order of  $5 \times 10^{-8}$ . No doubt the barium chloride was also being adsorbed, but this would be of no consequence as far as the radium adsorption is concerned. It thus appears that the same laws of adsorption apply to these minute quantities of radium that apply to the adsorption of ponderable masses of ordinary chemical substances.

When a radium barium chloride solution is incompletely precipitated by means of a soluble sulfate, such as sulfuric acid, the radium and barium come down in about the same proportion as they exist in the original solution, there being a slight concentration of the radium in the precipi-

tate. In other words, very little concentration of radium can be effected by a fractional precipitation method. Since the solubility of pure radium sulfate in water is so great that there could be no thought of a precipitation in the case of concentrations met with in the working up of radium ores, we are in the habit of speaking of the phenomenon of barium and radium precipitating together as adsorption. Looking at the question from the point of view of solubility product considerations, we could about as well explain the precipitation of the radium from the point of view of a salting out process which is brought about by the great excess of sulfate ions belonging to the dissolved barium. The fact that the adsorption law is followed in the case of the radium chloride would lead one to favor the adsorption theory in the case of a precipitation of the sulfate.

If we admit the validity of the adsorption theory in the case of a precipitation, the question arises as to why we can get a complete extraction of radium by means of a complete barium precipitation, whereas in the case of barium radium chloride in contact with barium sulfate we have an equilibrium radically different from what would be expected on the basis of the barium in solution compared to the barium present as sulfate. Thus 10 cc. of the standard solution contained about 0.04 g. of barium chloride. This solution, in contact with 0.05 g. of barium sulfate (of almost the same molecular weight as the radium sulfate) came to equilibrium with  $\frac{4}{5}$  of the radium adsorbed on 0.04 g. or about half of the barium. Again 0.04 g. of barium chloride in the solution in equilibrium with 0.5 g. of barium sulfate came to equilibrium with  $\frac{1}{7}$  of the radium adsorbed on  $\frac{1}{12}$  of the barium. Evidently this is something more than just a proportionate distribution of the radium with the barium.

A better understanding of these phenomena can be obtained if we consider for a moment the adsorption equation as modified by Freundlich.

$$x/m = \alpha c^{1/n} \quad (8)$$

where  $x$  and  $m$  have the same significance as before and  $c$  is the concentration at equilibrium, or  $\frac{a-x}{v}$ . The term  $m$  represents the mass of the adsorbent, and is used as a measure of the surface area of the adsorbent, to which it bears a definite relation, in the case of an adsorbent of given fineness. Hence the term  $x/m$  is in a way a measure of mass adsorbed per unit area of adsorbent. The constants  $\alpha$  and  $n$  are as mentioned above dependent only on the temperature and the nature of the dissolved substance. When we mix barium sulfate with a solution of barium radium chloride of known concentration, the area of the adsorbent is comparatively small. Since the concentration  $c$  is small and the area is small, the term  $x$  or the mass adsorbed will be finite. If on the other hand we precipitate barium sulfate from a solution of barium radium chloride, the area of

the adsorbent is tremendous, as the precipitate grows from about molecular dimensions. When the area becomes very large,  $\alpha$  must also become large in order to keep  $c$  finite. The result is a complete precipitation of the radium with the barium. If these considerations are valid, we might expect to be able to precipitate all of the radium before all of the barium has been thrown down. In other words we might expect to be able to carry on a fractional precipitation. This does not seem to be the case with radium, but it may be noted that it can be done with certain radio-active substances.<sup>3</sup> In this connection it is well to remember that adsorption is a specific property, depending not only on the adsorbent and the adsorbed substance, but also on the solvent.

We may make the above considerations clear by means of the following crude calculations. Let us assume that the diameter of the molecule is of the order of  $10^{-8}$  cm. Its area, assuming it to be spherical, would be about  $3 \times 10^{-16}$  sq. cm. There would be approximately  $10^{24}$  molecules per cc. of substance if we can assume close packing. Hence 1 cc. of solid substance of molecular sized particles would present an area of  $10^{24} \times 3 \times 10^{-16}$ , or  $3 \times 10^8$  sq. cm.

Now suppose we take the precipitated barium sulfate which was put through a 200-mesh sieve. Assuming the wire to have the same diameter as the hole, we would have holes 0.006 cm. square. Particles smaller than this also pass through. Let us therefore suppose, for the sake of argument, that the average particle passing through has a diameter of 0.002 cm. Its radius will be 0.001 cm., and its area approximately  $10^{-5}$  sq. cm. Of these particles there would be about  $10^8$  per cc. of solid substance, giving us a total area of  $10^8 \times 10^{-5}$ , or  $10^3$  sq. cm. We thus see that we have 1000 sq. cm. in the latter case as compared to three hundred million in the former. The former is three hundred thousand times the latter.

Regarding Equation 7 in the light of these figures we can readily see that  $\alpha$  must approach as a limiting value the total mass of substance dissolved which is capable of being adsorbed. As the area of the adsorbent (a number proportional to  $m$  in the general case) becomes very large, the concentration  $c$  must approach zero.

### Summary.

1. The adsorption law of Kroeker has been experimentally tested in the case of a radio-active substance and found to hold true.
2. The adsorption law of Freundlich has been experimentally tested and found to hold true in the case of a radio-active substance.
3. The same laws of adsorption which apply to the adsorption of ponderable masses are found to apply with an equal degree of accuracy to masses of  $5 \times 10^{-8}$  g. adsorbed per gram of adsorbent.

<sup>3</sup> Unpublished work of the author.

4. The relationship existing between adsorption taking place during precipitation, and that taking place on a solid precipitate of definite surface area has been discussed.

## THE SURFACE TENSIONS AND DENSITIES OF LIQUID MERCURY, CADMIUM, ZINC, LEAD, TIN AND BISMUTH.

By THORFIN R. HOGNESS.<sup>1</sup>

Received May 6, 1921.

The purpose of this investigation was to secure data for the examination of metallic solutions from the standpoint of the theory of solubility which has been outlined by Hildebrand and extensively applied by him and his co-workers<sup>2</sup> to non-metallic solutions. Although surface tension has proved to be a criterion of great value with non-metallic solutions, the evident inaccuracy of much of the data heretofore published upon the surface tensions of liquid metals has made the work herein described prerequisite to the accomplishment of the above purpose.

The method selected for our purpose is one originated by Cantor<sup>3</sup> and extensively applied by Jaeger<sup>4</sup> to non-metallic liquids. The method as it is generally employed consists in determining the pressure necessary to force a bubble of inert gas from the end of a sharp edged platinum capillary immersed in the liquid. On account of the impossibility of using a metallic capillary with liquid metals the process has been reversed in the present work so as to measure the pressure necessary to force a tiny drop from the tip of a quartz capillary directed upwards. The theory of this method is as follows.

The free surface energy of a sphere of liquid of surface  $s$  and surface tension  $\gamma$  is  $\gamma s$ . If the drop is increased infinitesimally in size by introducing more liquid, say, through a fine capillary, the work done against the surface tension is  $\gamma ds$ . This is equal to the pressure exerted by the tension upon the interior of the drop multiplied by the increase in volume  $dv$ , so that  $\gamma ds$  equals  $p dv$ . Since  $s = 4\pi r^2$  and  $v = \frac{4}{3}\pi r^3$ , we have  $\gamma = pr/2$ .

If we have a small capillary of radius  $a$  and apply pressure to force out a drop of the liquid, the radius of curvature of the drop will gradually

<sup>1</sup> Thesis presented in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

<sup>2</sup> Hildebrand, *This Journal*, 38, 1452 (1916); 39, 2297 (1917); 41, 1067 (1919); 43, 500 (1921). Hildebrand and Jenks, *ibid.*, 42, 2180 (1920). Hildebrand and Buehrer, *ibid.*, 42, 2213 (1920).

<sup>3</sup> Cantor, *Wied. Ann.*, 47, 399 (1892).

<sup>4</sup> Jaeger, *Z. anorg. Chem.*, 101, 1 (1917).

diminish as the pressure increases until it reaches a minimum value where  $r$  equals  $a$ . At this point the corresponding pressure will be a maximum, and it is this maximum pressure that is measured. The force of gravity causes a slight distortion of the drop necessitating a correction for the larger capillaries. This distortion is accounted for in the formula derived by Cantor, and corrected by Feustel,<sup>5</sup> where  $d$  is the density of the liquid.

$$= \frac{pa}{2} \left( 1 - \frac{2}{3} \frac{da}{p} - \frac{d^2 a^2}{p^2} \right)$$

This method has marked advantages over most others applicable to the metals in that it provides for a fresh and uncontaminated surface; it avoids the introduction of contact angle, which is necessary in the capillary depression method; it depends only upon primary standards; and it is free from theoretical uncertainties such as are involved in the drop-weight method.

### Description of Apparatus.

The apparatus finally adopted is shown in Fig. 1. The whole apparatus was built of Pyrex glass, with the exception of A which is a quartz capillary. The capillary was

Fig. 1.

sealed to the tube J by means of a cement consisting of zinc oxide and sodium silicate. B is a tube about 1 cm. in diameter into which a head of molten metal was raised. G is a reservoir for the metal and C, a tube for introducing a cast rod of the solid metal. E and F were sealed to different parts of a rather elaborate system providing for the independent and accurate control of the pressure of the hydrogen. It is necessary that the capillary be circular, have a sharp edge and that the edge be perpendicular to the axis. These conditions were obtained by selection from many hundreds of short sections cut from finely drawn tubes. Sharp edges and ends perpendicular to the axes of the capillaries were obtained by scratching the capillaries with a razor blade and breaking. The ends were ascertained to be perpendicular by examination under a microscope. The diameters of the capillaries were measured with a calibrated comparator. The capillaries were not exactly circular in cross section, but the ellipticity was, in all cases, very small. The mean radii and the respective percentage differences between the major and minor axes were as follows: 0.02127, 0.94%; 0.02574, 0.58%; 0.01814, 0.55%; 0.02125, 0.65%.

Expansion of the quartz with the temperature was a negligible factor. The apparatus was heated by means

<sup>5</sup> Robt. Feustel, *Ann. phys.*, [4] 16, 61 (1905).

accuracy of temperature control is unnecessary, since the simultaneous decrease in surface tension and density means that the head of liquid metal necessary to force a drop out of the capillary varies but slowly with temperature.

### Experimental Procedure.

Before each determination it was necessary to heat the apparatus at  $500^{\circ}$  for a few hours while being evacuated to remove the adsorbed water vapor. At first this adsorbed water gave considerable trouble, especially at temperatures over  $450^{\circ}$ , but this was finally overcome by the preliminary heating.

When the apparatus had again cooled, a cast rod of the metal was introduced into the tube C which was again sealed. After repeatedly evacuating and washing out the whole line with hydrogen, the apparatus was again heated until the metal in C melted and ran into the reservoir G. Pressure was gradually applied at F, raising the metal into the column B. The change in level of the surface H was followed with a cathetometer, and its height was noted at the instant when drops of metal began to flow out of the top of A. The difference in head between the tip of the capillary and the surface H, multiplied by the density of the metal, gives the maximum pressure necessary to force a drop out of the tip. Shaking of the building caused a premature breaking of the drop so it was necessary to work during the quieter hours of the day.

In some of the determinations there was a slight capillary depression of the metal in the tube B. The magnitude of this depression was determined at the same time as the densities by a method described below. All determinations, with the exception of one with mercury, were made in an atmosphere of hydrogen at pressures somewhat greater than the vapor pressures of the metals.

### Density Determinations.

To calculate the surface tension it was necessary to know the densities of the metals at different temperatures. The densities were determined by measuring the difference in height of the metal in the two arms of a U-tube caused by a measured pressure difference.

The apparatus was designed to fit the furnace used in the surface tension work and is shown in Fig. 2.

D and H are tubes 3.5 cm. in diameter, large enough to have a negligible capillary depression; A, a long tube for inserting a rod of the metal, and C is a tube of the same diameter as B of Fig. 1. The tube C was inserted to determine the correction for capillary depression to be added to the observed heights in the surface tension determinations. E and F were sealed to the line constructed for controlling and measuring the pressure. The difference in pressure in E and F was measured by means of a manometer filled with sulfuric acid, the density of which was accurately determined. The difference in level of the metal in D and H was measured with a cathetometer.

Fig. 2.

**Purification of Materials.**—Mercury was purified by washing and distilling c. p. mercury three times in accordance with methods recommended by Hulett.<sup>6</sup>

Bismuth was prepared by fusing twice reprecipitated bismuth oxychloride with pure potassium cyanide.

Electrolytic purification was used with the other metals, using anodes of as pure metal as was obtainable. The lead, tin and cadmium were pure commercial samples, the zinc from the Bertha mine of the New Jersey Zinc Company. The electrolytes were respectively lead perchlorate, stannic chloride, cadmium sulfate and zinc sulfate.

### Observations and Results.

**Densities.**—The following expressions represent the result of the density determinations. At least four temperatures were used with each substance. The maximum difference between the observed values and those calculated from the equations was 0.1%.

Zinc	$d = 6.59 - 0.00097(t - 419)$
Lead	$d = 10.71 - 0.00139(t - 327)$
Cadmium	$d = 8.02 - 0.00110(t - 320)$
Bismuth	$d = 10.07 - 0.00125(t - 269)$
Tin	$d = 7.01 - 0.00074(t - 232)$

**Surface Tensions.**—The data and the values of surface tensions calculated from the observations are given in Table I.

TABLE I.  
Observed Values of Surface Tension.

TABLE I.—(Continued).

	$^{\circ}$ C.	Press. H <sub>2</sub> mm.	No. of Observations.	Radius of capillary cm.	Aver. corrected height.	Density.	Surface tension. Dynes per cm.
	421	100	3		6.26	7.92	622
	448	145	8		6.28	7.88	621
	508	100	3		6.29	7.82	619
	544	145	7		6.29	7.78	616
Lead	366	6	7	0.02574	3.30	10.65	442
	444	6	9		3.27	10.55	433
	522	6	5		3.27	10.44	429
Tin	362		5	0.01814	8.58	6.99	530
	319		6		8.46	6.95	519
	396		6		8.52	6.89	520
Zinc	477		5	0.02125	11.07	6.53	753
	543		9	0.02125	11.09	6.47	747

The maximum deviation from the averages here given was about 1% and in nearly all instances was very much less. The values for the surface tension of cadmium diminish with temperature below  $421^{\circ}$ , *i. e.*, the surface tension appears to go through a maximum. These values for cadmium were checked to within 1% by an independent determination using a different capillary but the duplicate set of values is not recorded in the table.

The values in Table I were plotted and the smooth curves drawn through the points are represented by the following equations. Only in the case of mercury does the range of temperature justify more than a linear equation. Fig. 3 gives the plot for mercury.

x-Values obtained with capillary of radius 0.02127 cm.

o-Values obtained with capillary of radius 0.01814 cm.

Fig. 3.

Mercury	$r = 467 - 0.043(t + 39) - 0.000386(t + 39)^2$
Bismuth	$r = 378 - 0.063(t - 269)$
Cadmium	$r = 630 - 0.065(t - 320)$
Lead	$r = 444 - 0.077(t - 327)$
Tin	$r = 531 - 0.080(t - 232)$
Zinc	$r = 758 - 0.090(t - 419)$

The first constant in the right hand member of each of the above equations represents the extrapolated values of the surface tension at the melting point. The equation for cadmium is determined only from the values at 421° and above.

Table II gives values of surface tension calculated at a series of temperatures from the smooth curves.

<sup>7</sup> B. Quincke, *Pogg. Ann.*, 135, 642 (1868); 138, 141 (1869).

<sup>8</sup> Siedentopf, *Wied. Ann.*, 61, 235 (1897).

<sup>9</sup> S. W. Smith, *J. Inst. Metals*, 12, 168 (1914).

<sup>10</sup> Grundmach, *Ann. Phys.*, 3, 660 (1900).

Quincke used a modification of the drop-weight method which consisted in the melting of metal from a wire of known diameter. With mercury and tin, the usual drop weight was employed. The values given in the table have been corrected by the use of the formula of Lohnstein.<sup>11</sup> The correction is of doubtful accuracy, the experimental procedure was crude, and the metal surfaces undoubtedly contaminated by oxide so that the figures can hardly claim great weight.

The values by Siedentopf were calculated from the dimensions of a drop resting upon a flat surface in an atmosphere of carbon dioxide which would undoubtedly produce contamination of the surface with oxide, as is indicated by the high values.

Smith used the capillary depression method with a hole drilled in a piece of carbon. He made no correction for the angle of contact, which is certainly greater than zero, so that his low results are not surprising.

Grundmach measured the wave length of ripples upon the flat metallic surface, a method difficult to use with accuracy. He worked in an atmosphere of air which undoubtedly vitiates his figures for tin.

The surface tension of mercury has been determined by almost all of the known methods, and the values vary from 340 to 575 dynes per centimeter. The different determinations have been made *in vacuo* and in various gases. Quincke<sup>12</sup> has given a summary of all the earlier work with mercury.

More recently, Cenac,<sup>13</sup> using the drop-weight method, with two different correction terms, Lohnstein's and Rayleigh's, has given the following values for mercury:

	0° C. (air).	(Vacuum.).	100° (vac.).	180° (vac.).
Lohnstein.....	437	460	437	419
Rayleigh.....	445	467	443	425

The values *in vacuo* at 0°, agree well with ours, but at higher temperatures the values fall off somewhat more rapidly. Cantor using the method employed in this research obtained 459 dynes at 20° in air, and using the inverse procedure of blowing a bubble of air from a capillary immersed in the mercury obtained 466 dynes at 20° in air. Richards and Boyer,<sup>14</sup> by measuring the dimensions of a drop, found 441 dynes in air, a value considerably lower than ours. Harkins and Ewing,<sup>15</sup> using the drop weight method, give 476 dynes *in vacuo*, and Harkins and Grafton<sup>16</sup> 465 dynes in air.

<sup>11</sup> Lohnstein, *Ann. phys.*, 20, 237 (1906).

<sup>12</sup> Quincke, *Ann. phys.*, 61, 267 (1897).

<sup>13</sup> Cenac, *Ann. chim. phys.*, 28, 298 (1913).

<sup>14</sup> T. W. Richards and S. Boyer, *THIS JOURNAL*, 43, 274 (1921).

<sup>15</sup> Harkins and Ewing, *ibid.*, 42, 2539 (1920).

<sup>16</sup> Harkins and Grafton, *ibid.*, 42, 2534 (1920).

Since some observers claim lower results in air than *in vacuo*, it might be questioned whether the hydrogen present in the apparatus may not have somewhat altered the values. This point was tested by varying the pressure of hydrogen from 300 mm. down to a vacuum giving the green fluorescence of the glass with the electric discharge. The hydrogen was also replaced by an atmosphere of dry air. No detectable difference in the surface tension was found. In view of the large overvoltage of hydrogen on mercury, it would hardly be expected that it could be appreciably adsorbed. It was found, however, that, for some unknown reason, the first readings of these determinations gave low values. These values gradually increased as the determination proceeded and finally reached a limit for which the readings were very constant and concordant. It was also found that, unless all water vapor was removed from the apparatus and mercury by previous heating, results 3 or 4% too low, were obtained.

It should be pointed out that the method here employed avoids the large and somewhat uncertain correction for the diameter of the capillary necessitated by the drop-weight method. The correction factor in the drop-weight method, the  $f(r/a)$  developed by Lohnstein<sup>11</sup> and the  $f(r/V^{1/3})$  used by Harkins<sup>17</sup> is often as small as 0.6 and does not approach the limiting value of unity, while in the Cantor method, the correction term deviates only very slightly from this limiting value. In the present research for all the capillaries used, the correction factor

$$\left( 1 - \frac{2}{3} \frac{da}{p} - \frac{d^2 a^2}{p^2} \right)$$

was greater than 0.99.

### Summary.

The densities of liquid zinc, cadmium, tin, lead and bismuth have been determined at various temperatures.

The surface tension of mercury, cadmium, zinc, lead, tin and bismuth have been determined by the Cantor method of drop pressure.

It has been shown that there is no appreciable difference in the surface tensions of mercury in dry air, hydrogen and *in vacuo*.

In conclusion the writer wishes to express his sincere appreciation to Professor J. H. Hildebrand, under whose direction the present work was carried on.

## NOTES.

**A New Type of Sodium Lamp for Polarimetry.**—To those persons who make use of a polariscope in their work the need of a constant and intense source of sodium light is one that is greatly felt. In this respect the authors believe that they have made a decided improvement by devising a simple arrangement which has served their purpose most admirably. Instead of any modification of the schemes used heretofore<sup>1</sup> they employ an alundum thimble or crucible as a reservoir for the salt which should preferably be sodium chloride. The thimble is exposed to the flame and as a result the sodium chloride melts, flows through the pores of the thimble and is vaporized in the flame so as to give a very intense illumination. The supply of material is large enough to insure a continuous source of light over a period of observation even to the extent of 5 or 6 hours if necessary. It is to be remarked, however, that in using this flame as with other sodium flames it is necessary for very precise work to use a dichromate light filter.

The general arrangement is portrayed in the accompanying sketch; while the details are discussed in the text under the three captions of shade, thimble and burner.

**Shade.**—The shade of the lamp is constructed of hard asbestos boarding about 3 to 4 mm. in thickness, the sides being bound by nickel or nickel-chromium wire passing through holes bored for this purpose. This shade is 14 cm. in height and 7.5 cm. square. A hole 3 cm. in diameter and 3.5 cm. from the bottom is cut in front, and constitutes the window for the light. On each side of the shade, 2.5 cm. from the back and extending to within 3.5 cm. from the bottom, are cut slits which allow the wire and suspended thimble to be lifted up and down, or removed and replaced at will. The whole shade is fastened at its bottom edge by wires to an iron ring which is movable up or down on a ring stand. This arrangement allows the adjustment of the shade with respect to the optical axis of the polariscope.

**Thimble.**—The alundum thimble should have a medium porosity; if the pores are too fine the molten sodium chloride filters through the thimble so slowly that the rate of vaporization is not enough to give proper intensity to the light; if the pores are too large the molten salt filters through the alundum more rapidly than it is vaporized and drops on the burner below. The thimble is suspended primarily by means of a silica tube which passes over a stout nickel or nickel-chromium wire.<sup>2</sup> The tube not only

<sup>1</sup> For a description of the various types of sodium light sources the reader is referred to Landolt, "Optical Rotation of Organic Substances," 1898, pp. 393-399. Browne, "Handbook of Sugar Analysis," 1912, pp. 147-149. Bur. Standards, *Bull.* No. 44 (Polarimetry), pp. 14-15 and 30-33 (1918).

<sup>2</sup> The silica tube can be obtained from a triangle made of this type of tubing.

protects the salt from contamination by the wire, but also protects the wire from the heat of the flame, thus preventing sagging. The holes in the alundum thimble, through which the silica tube passes, are easily and quickly bored with a rat-tail file or other sharp instrument, while the thimble itself can be cut down quickly to any size by means of a triangular file. The height of the thimble should be such that its top is in the same horizontal plane as the bottom of the window in the shade.

**Burner.**—The burner, which should preferably be of the Meker type, rests upon a movable platform attached to the same ring stand as the shade. The burner should be placed in such a position with respect to the thimble that the flame is not distorted by too close proximity, and so that the rear portion of the flame encounters the front part of the thimble.

**The Thermal Ionization of Metallic Vapors.**<sup>1</sup>—In a preceding paper,<sup>2</sup> the author has shown that the entropy of electron gas may be calculated from the same theoretical equation as for the other monatomic gases, namely,

$$S = \frac{5}{2} R \ln T - R \ln p + \frac{3}{2} R \ln M + S_1$$

where  $M$  is the molecular weight of the monatomic gas and  $S_1$  has the same value for all monatomic gases. Taking  $p$  in atmospheres,  $S_1$  has the value  $-3.2$  calories per degree.

This new theoretical knowledge may be used in predicting the thermal ionization of metallic vapors, a matter of some interest from the point of view of physical chemistry and astronomy.

**Derivation of Free Energy Equation for Ionization.**—Consider a metallic vapor which can dissociate into a positive ion and an electron in accordance with the reaction,

For the heat of the reaction of constant pressure and at temperature  $T$  we may evidently write,

$$\Delta H = EF + \frac{5}{2} RT \quad (2)$$

where  $E$  is the ionization potential of the metal in question,  $F$  is the value of the faraday,  $EF$  being the increase in the heat content of the system at the absolute zero, and  $\frac{5}{2} R T$  the value of  $\Delta C_p T$ .

For the change in the entropy of the system when the reaction occurs at constant temperature and under the standard conditions of unit partial pressure for each of the three components, we may obviously write from Equation 1,

$$\Delta S = \frac{5}{2} R \ln T + \frac{3}{2} R \ln M_E + S_1 \quad (3)$$

<sup>1</sup> Published by permission of the Chief of Ordnance.

<sup>2</sup> Tolman, *THIS JOURNAL*, **43**, 1592 (1921).

where  $M_{\pm}$  is the molecular weight of electron gas and we have neglected the slight difference between the molecular weights of the un-ionized vapor and its positive ion.<sup>3</sup>

We have thus obtained simple expressions (2) and (3) for the heat change and entropy change accompanying the reaction in which we are interested. We have, however, the following fundamental equation of definition connecting free energy with heat content and entropy, namely,

$$\Delta F = \Delta H - T \Delta S \quad (4)$$

Introducing (2) and (3) we obtain,

$$\Delta F = EF - \frac{5}{2} R T \ln T + \left( \frac{5}{2} R - \frac{3}{2} R \ln M_{\pm} - S_1 \right) T. \quad (5)$$

It is interesting to note that this equation has the same form as that of the familiar free energy equation,

$$\Delta F = \Delta H_0 - \Delta C_p T \ln T + I T$$

and the corresponding quantities have precisely the same significance.

**Calculation of Ionization Constant.**—In order to determine the degree of ionization of the vapor we may substitute Equation 5 into the well-known expression connecting free energy change with equilibrium constant,

$$\Delta F = -R T \ln K_p = -R T \ln \frac{p_{R^+} p_{E^-}}{p_R}. \quad (6)$$

We obtain,

$$\ln K_p = -\frac{EF}{RT} + \frac{5}{2} \ln T - \left( \frac{5}{2} - \frac{3}{2} \ln M_{\pm} - \frac{S_1}{R} \right). \quad (7)$$

If  $K_p$  is the equilibrium constant using partial pressures expressed in atmospheres,  $E$  is the ionization potential in volts,  $T$  is in degrees Kelvin, and we change to common logarithms and use the values  $F = 96540$  coulombs,  $M_{\pm} = 5.44 \times 10^{-4}$  grams,  $S = -3.2$  calories per degree and  $R = 1.985$  calories per degree we obtain,

$$\log K_p = -\frac{5040 E}{T} + 2.5 \log T - 6.69. \quad (8)$$

**Ionization of Calcium Vapor in the Sun's Atmosphere.**—The use of this equation in predicting the degree of ionization of metallic vapors in the electric arc or the atmosphere of the sun will be obvious.

For example, if we take the ionization potential of calcium vapor as 6.1 volts, the partial pressure of un-ionized calcium vapor in the sun's

<sup>3</sup> Equation 3 involves the assumption that we are justified in considering all three gases  $R$ ,  $R^+$  and  $E^-$  as monatomic even at the high temperatures involved. It is of course possible that the atoms of the metallic vapor would pick up rotational energy at high temperatures and hence that their entropy should be calculated from the formula for a diatomic or polyatomic gas.

atmosphere as 4 atmospheres, and the temperature as  $5500^{\circ}$  absolute, the partial pressure of calcium ion or of electron gas comes out 0.07 atmospheres corresponding to 1.7% ionization. This means that the sun's atmosphere has a very considerable electrical conductivity which can be calculated by making proper estimates of the ionic mobilities.

## AROMATIC ARSENIC COMPOUNDS. IX. DIAZO-AMINO COMPOUNDS OF ARSANILIC ACID AND ITS DERIVATIVES.

BY WALTER A. JACOBS AND MICHAEL HEIDELBERGER.

Received June 29, 1920.

In a former communication<sup>1</sup> there was outlined a plan for the synthesis of aromatic arsenic compounds for chemotherapeutic study in which, among other series of substances which have since been published, were mentioned the two groups of diazo-amino and azo derivatives obtained from arsanilic acid. These substances with the first which we prepared for these investigations, and although interesting results were obtained with individual compounds in the treatment of experimental trypanosomiasis, we were soon led to discontinue the study of these types because of disadvantages which seemed inherent in them, such as the general instability of the diazo-amino compounds and certain harmful toxic effects induced by both groups. We believe, however, that a presentation of our chemical studies with these compounds should not be devoid of interest.

<sup>1</sup> *THIS JOURNAL*, 41, 1581 (1919).

In their determination of the constitution of arsanilic acid Ehrlich and Bertheim<sup>2</sup> found that the amino group could be readily diazotized and that the resulting diazo compound coupled without difficulty, yielding azo dyes. We have found that this reaction could be extended to the preparation of well-defined diazo-amino compounds containing the arsonic acid residue. We have prepared several groups of such substances, using as couplers dialkylamines, simple arylamines, aminobenzoic acids, arylglycines, and amino-phenoxyacetic acids.

The coupling of the secondary aliphatic amines and the simpler primary aromatic amines with diazotized arsanilic acid offered as a rule but little difficulty, the procedure being that adopted in the past for analogous substances. The reaction mixture was kept neutral or acid only with a weak acid such as acetic acid. The isolation of the individual compounds was accomplished either as the salt or as the acid, depending upon manipulative convenience. In certain cases it was found preferable, however, to diazotize the amino compound first and then to add arsanilic acid as the coupler. In the case of the aromatic amino acids, although coupling usually proceeded smoothly, it required considerable experimentation to determine in what form and under what conditions the product could best be isolated, since there were available the free acid, the monosodium salt, and the disodium salt from which to choose. The simpler aminobenzoic acids yielded diazo compounds under carefully controlled conditions by using the amino acid itself as coupler and isolating the products as the monosodium salts. In the first experiments in which *p*-amino-phenoxyacetic acid and its homologs were employed, however, it developed that the reaction either did not proceed entirely in the desired sense, or that the diazo-amino compounds possessed properties which rendered difficult their isolation from the reaction mixture. In such cases it was found that the amino acid esters coupled smoothly, giving the diazo-amino esters in excellent yield. Owing to the stability of the diazo-amino group on the alkaline side it then proved relatively simple to saponify the esters to the diazo-amino acids themselves. This method was consequently employed as a more certain means of obtaining these acids in satisfactory form and yield from the more complex amino-aryl acids, although in some instances the direct method might have been employed. This device also proved necessary in the preparation of the diazo-amino compound from *p*-aminophenol. Here *p*-aminophenyl benzoate was diazotized and coupled with arsanilic acid, yielding the diazo-amino benzoate, which was subsequently saponified.

The diazo-amino compounds derived from the secondary aliphatic amines and from most of the aromatic amino compounds formed both crystalline acids and sodium salts, the former possessing definite decompo-

<sup>2</sup> Ehrlich and Bertheim, *Ber.*, 40, 3292 (1907).

sition points and being as a rule difficultly soluble in the usual solvents, while the salts formed more or less yellow solutions in water. The acids were unstable in acid solution, readily dissociating into the component amino and diazo compounds and evolving nitrogen on warming. In the case of several of the diazo-amino compounds derived from the arylglycines and the methyl derivatives of *p*-amino-phenoxyacetic acid, it was found impossible to isolate the free acids owing to their slight tendency to crystallize and to the ease with which they dissociated in acid solution. On the other hand, the esters of these substances, with few exceptions, proved to be more stable and easy to isolate. Practically all of the diazo-amino sodium salts were readily soluble in water, the solutions giving immediate precipitates with the heavy metal ions.

On the whole the work with this class of substances proved difficult, since in each case the conditions best suited for the preparation and isolation of the particular compound had to be carefully studied. It was also found essential to work as rapidly as possible throughout, and at low temperatures in order to avoid the decomposition which otherwise readily occurred.

Owing to the mass of detail the work is presented practically in abstract form, in order not to use undue space.

### Experimental.

The values given for water of crystallization were obtained with substances which had been dried to constant weight in the air. Water was determined as a rule by drying *in vacuo* at room temperature over sulfuric acid, since higher temperatures caused decomposition.

In order to avoid repetition, it will be understood that the diazotization of arsanilic acid was carried out as follows. Arsanilic acid was dissolved in 2 molecular equivalents of *N* hydrochloric acid, chilled to about 5° and diazotized with one equivalent of 5 *N* sodium nitrite solution. The reaction proceeded smoothly and completely and toward the end there was a pronounced color change from orange to pale yellow. The solution was then neutralized before coupling according to the method given under each compound to be described. The expression  $A \rightarrow B$  indicates that the diazotized arsanilic acid solution was added to the coupler;  $B \rightarrow A$ , that the coupler was added to the diazotized arsanilic acid.

In cases in which no acid group was present in addition to the arsonic acid residue, acetic acid was in all cases sufficient to liberate the diazo-amino arsonic acid from solutions of the sodium salt. It was also found advantageous to work at rather high dilutions, except in the case of the aliphatic amines. When an additional carboxy group was present it was found necessary to add to the chilled solutions of the salt sufficient hydrochloric acid to render the reaction just acid to congo red.

## (A) Diazo-amino Compounds of Arsanilic Acid and Aliphatic Amines.

**Diazobenzene - (4-arsonic acid) - dimethylamine.**—B  $\longrightarrow$  neutralized A, coupling being complete in about 15 minutes. After adding acetic acid the product was recrystallized from alcohol, forming orange spears which intumesced at 182°. It is very difficultly soluble in cold alcohol, more readily in methyl alcohol, and decomposes in boiling water with nitrogen evolution.

*Analyses.* Calc. for  $C_8H_{12}O_3N_3As$ : N, 15.38; As, 27.44. Found: N, 15.52; As, 27.13.

On treating an alcoholic suspension with 1 mol. of 25% sodium hydroxide solution, heating, and carefully adding water until clear, the sodium salt crystallized on cooling, separating from 85% alcohol as glistening, salmon-colored platelets which dissolve easily in water.

*Analyses.* Calc. for  $C_8H_{11}O_3N_3AsNa \cdot 3.5H_2O$ :  $H_2O$ , 17.60. Found: 17.89.

Calc. for  $C_8H_{11}O_3N_3AsNa$ : N, 14.24. Found: 14.42.

**Diazobenzene - (4-arsonic acid) - diethylamine.**—The crude acid was reprecipitated from dil. sodium carbonate, dissolved in warm 50% alcohol, and cautiously diluted with an equal volume of water, separating as delicate, flat, cream-colored needles, which, when anhydrous, gradually soften and darken above 120°, decompose at about 195–200°, and dissolve readily in methyl alcohol and acetic acid.

*Analyses.* Calc. for  $C_{10}H_{16}O_3N_3As \cdot H_2O$ :  $H_2O$ , 5.65. Found: 6.51.

Calc. for  $C_{10}H_{16}O_3N_3As$ : N, 13.96; As, 24.88. Found: N, 13.59; As, 25.12.

A neutral aqueous solution of the sodium salt was prepared, evaporated to dryness *in vacuo*, and the residue dissolved in a little hot 85% alcohol, the salt slowly crystallizing in the cold as rosetts of somewhat deliquescent cream-colored needles.

*Analyses.* Calc. for  $C_{10}H_{16}O_3N_3AsNa$ : N, 13.00; As, 23.21. Found: N, 13.02; As, 23.82.

**Diazobenzene - (4-arsonic acid) - piperidine.**—The free acid, obtained from its salt, formed pale drab spherules and rosetts of narrow, microscopic platelets which melt and effervesce at 162–3°, and are appreciably soluble in methyl and ethyl alcohol.

*Analyses.* Calc. for  $C_{11}H_{16}O_3N_3As$ : N, 13.42; As, 23.93. Found: N, 13.53; As, 23.69.

Separation of the sodium salt from the initial reaction mixture was facilitated by the addition of sodium acetate. It forms drab-colored, minute platelets from 85% alcohol.

*Analyses.* Calc. for  $C_{11}H_{16}O_3N_3AsNa \cdot 3.5H_2O$ :  $H_2O$ , 15.83. Found: 15.35.

Calc. for  $C_{11}H_{16}O_3N_3AsNa$ : N, 12.53. Found: 12.57.

**Bis-diazobenzene - (4-arsonic acid) - pentamethylene-tetramine.**—8.7 g. of arsanilic acid were diazotized with 40 cc. of *N* sodium nitrite solution, diluted with an equal volume of saturated sodium acetate solution, and then treated with 3 g. of hexamethylene-tetramine.<sup>3</sup> Coupling occurred rapidly with cleavage of formaldehyde, and 8 g. of the sodium salt quickly crystallized. Rapid recrystallization from water yielded lustrous, colorless platelets soluble in about 20 parts of water at ordinary temperatures.

*Analyses.* Calc. for  $C_{17}H_{20}O_6N_8As_2Na_2 \cdot 6H_2O$ :  $H_2O$ , 14.68. Found: 14.31.

Calc. for  $C_{17}H_{20}O_6N_8As_2Na_2$ : N, 17.83. Found: 17.65.

On slowly treating a very dilute solution in warm water with acetic acid the free acid separates as narrow, minute, colorless, microscopic platelets which are practically insoluble in neutral solvents. It puffs up at 210–12°, and dissolves very slowly in boiling water with nitrogen evolution, decomposition occurring rapidly on addition of a drop of acid, when the odor of formaldehyde becomes quite noticeable.

*Analyses.* Calc. for  $C_{17}H_{20}O_6N_8As_2$ : N, 19.18; As, 25.66. Found: N, 19.15; As, 25.40.

<sup>3</sup> Cf. Duden and Scharf, *Ann.*, 288, 218 (1895).

## (B) Diazo-amino Compounds of Arsanilic Acid and the Simpler Aromatic Amines.

**Diazobenzene - 4-(arsonic acid) - aniline.**—Alcoholic B  $\longrightarrow$  neutralized A. The yellow sodium salt gradually crystallized on adding sodium acetate, separating from 85% alcohol as minute, orange platelets and flat needles which dissolve readily in water.

*Analyses.* Calc. for  $C_{12}H_{11}O_3N_3AsNa \cdot 4H_2O$ :  $H_2O$ , 17.35. Found: 17.02.

Calc. for  $C_{12}H_{11}O_3N_3AsNa$ : N, 12.24. Found: 12.21.

The free acid forms bundles of minute, yellow, microscopic needles which melt and then decompose at 112–13°. It is difficultly soluble in cold methyl and ethyl alcohols but quite readily on boiling, and decomposes in boiling water.

*Analyses.* Calc. for  $C_{12}H_{12}O_3N_3As$ : N, 13.08; As, 23.33. Found: N, 12.77; As, 23.55.

**Diazobenzene - (4-arsonic acid) - methylaniline.**—Alcoholic B  $\longrightarrow$  A + sodium acetate yielded a brown, gummy precipitate which crystallized on rubbing. On dissolving in very dilute aqueous ammonia, adding an equal volume of alcohol, cooling, and acidifying with acetic acid, the pure acid separated as orange-brown aggregates of minute radiating needles, effervescing at 160–2° with preliminary reddening. It dissolves in dil. acid with an orange-red color appearing a faint purple in thin layers, apparently due to partial dye formation, although the solution still evolves nitrogen on heating.

*Analyses.* Calc. for  $C_{13}H_{14}O_3N_3As$ : N, 12.54. Found: 12.58.

When the diazo solution was neutralized with sodium hydroxide and then coupled with methylaniline, a deep brown-orange solution resulted from which the sodium salt separated on adding sodium acetate, as a thick paste of lustrous, orange platelets which were recrystallized from water.

*Analyses.* Calc. for  $C_{12}H_{13}O_3N_3AsNa \cdot 5.5H_2O$ :  $H_2O$ , 21.70. Found: 21.53.

Calc. for  $C_{13}H_{13}O_3N_3AsNa$ : N, 11.76; As, 21.00. Found: N, 11.83; As, 21.30.

**Diazobenzene - (4-arsonic acid) - p - toluidine.**—The sparingly soluble sodium salt separated in almost quantitative yield, forming yellow, glistening leaflets from water containing a few drops of dil. sodium carbonate.

*Analyses.* Calc. for  $C_{13}H_{13}O_3N_3AsNa \cdot 6H_2O$ :  $H_2O$ , 23.23. Found: 22.79.

Calc. for  $C_{13}H_{13}O_3N_3AsNa$ : N, 11.76; As, 20.99. Found: N, 11.78; As, 20.79.

The free acid is precipitated from a 50% alcoholic solution of the salt as thin, pale yellow, microscopic needles which intumesce at 130–2° and dissolve in hot alcohol.

*Analysis.* Calc. for  $C_{13}H_{14}O_3N_3As$ : N, 12.53. Found: 12.63.

**Diazobenzene - (4-arsonic acid) - 4' - chloro-aniline.**—B + dil. hydrochloric acid  $\longrightarrow$  A + sodium acetate. The acid immediately precipitated in quantitative yield and gradually crystallized. Dissolved in much 50% alcohol with the aid of sodium hydroxide and re-acidified it forms an emulsion which rapidly changes on rubbing to hexagonal platelets which intumesce at 177° with preliminary darkening and are practically insoluble in neutral solvents.

*Analysis.* Calc. for  $C_{12}H_{11}O_3N_3ClAs$ : N, 11.82. Found: 12.08.

Dissolved in 1 mol. of dil. sodium hydroxide solution it yielded the sodium salt on addition of alcohol, forming almost colorless platelets from 50% alcohol.

*Analyses.* Calc. for  $C_{12}H_{10}O_3N_3ClAsNa \cdot 2H_2O$ :  $H_2O$ , 8.71. Found: 8.37.

Calc. for  $C_{12}H_{10}O_3N_3ClAsNa$ : N, 11.12; As, 19.86. Found: N, 11.20; As, 20.01.

**Diazobenzene - (4-arsonic acid) - o - anisidine.**—Although Jacobson and Hönigsberger<sup>4</sup> obtained a dye in using o-anisidine as a coupler, the method used in the above cases yielded the diazo-amino derivative. A certain amount of dye formation was, however, evident from the deep color. The sodium salt was salted out with sodium

<sup>4</sup> Jacobson and Hönigsberger, *Ber.*, 36, 4096 (1903).

acetate and washed with alcohol. It separates from 85% alcohol as aggregates of brown, rectangular platelets dissolving readily in water.

*Analyses.* Calc. for  $C_{13}H_{13}O_4N_3AsNa \cdot 5H_2O$ :  $H_2O$ , 19.44. Found: 20.02.

Calc. for  $C_{13}H_{13}O_4N_3AsNa$ : N, 11.26. Found: 11.19.

The free acid was precipitated from a chilled solution of the salt in 50% alcohol as sheaves of flat, microscopic needles which, when anhydrous, sinter, then darken, and finally intumesce at 95–9°.

*Analyses.* Calc. for  $C_{13}H_{14}O_4N_3As \cdot 2.5H_2O$ :  $H_2O$ , 11.37. Found: 10.58.

**Diazobenzene - (4-arsonic acid) - 4' - aminophenyl benzoate.**—6.4 g. of well powdered *p*-aminophenyl benzoate<sup>5</sup> suspended in 60 cc. of *N* hydrochloric acid were slowly diazotized at 10° with 2.2 g. of sodium nitrite. After 15 minutes' additional turbing the solution was filtered from a small amount of undissolved material and then treated, with stirring, with 6.6 g. of arsanilic acid in 30 cc. of *N* sodium hydroxide solution. The light yellow, pasty diazo-amino compound solidified completely on standing overnight in the ice-box. The yield was 12 g. A portion, dissolved in a large volume of warm methyl alcohol and cautiously treated with water until crystallization began on rubbing, formed thin, yellow, microscopic leaflets which decompose at 155–8° and are practically insoluble in neutral solvents except hot methyl and ethyl alcohols.

*Analysis.* Calc. for  $C_{19}H_{19}O_6N_3As$ : N, 9.52. Found: 9.65.

**Diazobenzene - (4-arsonic acid) - 4' - aminophenol.**—The crude benzoate was dissolved in 4 equivalents of 2 *N* sodium hydroxide solution, allowed to stand for 15 minutes at room temperature, saturated with sodium acetate, and then chilled and neutralized with acetic acid. On rubbing the sodium salt slowly crystallized, separating from 85% alcohol as rosetts of yellow microscopic needles. Under carefully controlled conditions acetic acid precipitated the microcrystalline acid which, however, was too unstable to isolate.

*Analyses.* Calc. for  $C_{12}H_{11}O_4N_3AsNa \cdot 4H_2O$ :  $H_2O$ , 16.69. Found: 16.38.

**Diazobenzene - (4-arsonic acid) - 4' - amino-acetophenone.**—A + 1 mol. alkali → diazotized B + sodium acetate. The resulting sodium salt, recrystallized from 85% alcohol, formed brownish-yellow rosetts of minute, flat needles.

*Analyses.* Calc. for  $C_{14}H_{13}O_4N_3AsNa \cdot 6H_2O$ :  $H_2O$ , 21.91. Found: 21.51.

<sup>5</sup> Cf. Wohl, *Ber.*, 36, 4143 (1903).

Calc. for  $C_{14}H_{13}O_4N_3AsNa$ : N, 10.91. Found: 10.94.

The free acid consists of sheaves of bright yellow, microscopic needles which intumesce to a reddish mass at  $177-8^\circ$  after preliminary darkening and sintering, and dissolve in boiling methyl alcohol.

*Analyses.* Calc. for  $C_{14}H_{14}O_4N_3As$ : N, 11.57; As, 20.63. Found: N, 11.40; As, 20.91.

### (C) Diazo-amino Compounds of Arsanilic Acid and the Aminobenzoic Acids.

**Diazobenzene - (4-arsonic acid) - 2' - aminobenzoic acid.**—Only the following conditions were found to yield this substance and its salts in pure form. 8.7 g. of arsanilic acid diazotized in 80 cc. of *N* hydrochloric acid were treated with 80 cc. of saturated sodium acetate solution and then with 5.5 g. of anthranilic acid dissolved in 80 cc. of *N* sodium hydroxide solution. The monosodium salt soon separated in almost quantitative yield as a brownish-yellow powder. On dissolving in dil. sodium hydroxide solution, adding sodium acetate and then a slight excess of acetic acid, a gelatinous mass formed which rapidly changed to radiating masses of flat, yellow microscopic needles of the monosodium salt. The substance is difficultly soluble in cold water.

*Analyses.* Calc. for  $C_{13}H_{11}O_5N_3AsNa \cdot 4.5H_2O$ :  $H_2O$ , 17.31. Found: 16.74

Calc. for  $C_{13}H_{11}O_5N_3AsNa$ : N, 10.85. Found: 11.06.

A concentrated solution prepared with an additional mol. of sodium hydroxide yielded with sodium acetate the yellow disodium salt which crystallized from 85% alcohol as long, flat, yellow needles, dissolving easily in water with a yellow color.

*Analyses.* Calc. for  $C_{13}H_{10}O_5N_3AsNa_2 \cdot 8H_2O$ :  $H_2O$ , 26.05. Found: 26.37.

Calc. for  $C_{13}H_{10}O_5N_3AsNa_2$ : N, 10.26; As, 18.32. Found: N, 10.14; As, 17.

With a large excess of acetic acid, it immediately gives the free acid as thin, yellow, microscopic needles which intumesce at  $160^\circ$ , and dissolve in hot methyl or ethyl alcohol.

*Analysis.* Calc. for  $C_{13}H_{13}O_5N_3As$ : N, 11.51. Found: 11.51.

**Diazobenzene - (4-arsonic acid) - 3' - aminobenzoic acid.**—The same conditions were used, except that the addition of 12 cc. of 50% acetic acid was necessary to cause the precipitation of the monosodium salt. Recrystallized as in the preceding preparation it forms a cream-colored, microcrystalline, anhydrous salt.

*Analysis.* Calc. for  $C_{13}H_{11}O_5N_3AsNa$ : N, 10.85. Found: 10.71.

An aqueous suspension was dissolved with just sufficient sodium hydroxide and treated with absolute alcohol to incipient turbidity. The resulting disodium salt separated from 70% alcohol as long, thin, pale yellow, microscopic needles.

*Analyses.* Calc. for  $C_{13}H_{10}O_5N_3AsNa_2 \cdot 6.5H_2O$ :  $H_2O$ , 22.24. Found: 21.68.

Calc. for  $C_{13}H_{10}O_5N_3AsNa_2$ : N, 10.26. Found: 10.32.

A well chilled solution in 50 parts of 50% alcohol was made just acid to congo red, the arsonic acid then separating as buff-colored microcrystalline rosetts which intumesce at  $141^\circ$  and dissolve in hot methyl and ethyl alcohols.

*Analyses.* Calc. for  $C_{13}H_{13}O_5N_3As$ : N, 11.51; As, 20.52. Found: N, 11.29; As, 20.54.

**Diazobenzene - (4-arsonic acid) - 4' - aminobenzoic acid.**—The special conditions necessary were treatment of the well chilled diazotate from 4.4 g. of arsanilic acid in 40 cc. of *N* hydrochloric acid with 60 cc. of alcohol and then rapidly with a solution of 2.8 g. of *p*-aminobenzoic acid in 10 cc. of 2 *N* sodium hydroxide solution. The deep brown solution deposited the yellow, amorphous monosodium salt almost at once and this changed to aggregates of microscopic needles under 50% alcohol. It was dissolved in 50% alcohol with a little sodium hydroxide and again acidified with acetic acid in slight excess, crystallizing in anhydrous form on rubbing. It is very sparingly soluble in cold water. The free acid formed flat, microscopic needles, but was not obtained pur

*Analyses.* Calc. for  $C_{13}H_{11}O_6N_3AsNa$ : N, 10.85; As, 19.36. Found: N, 11.07; As, 19.23.

**Diazobenzene - (4-arsonic acid) - 3' - amino-6'-methoxybenzoic methyl ester.**—B hydrochloride  $\rightarrow$  A + sodium acetate. The resulting thick, gelatinous mass crystallized after adding one-half volume of alcohol and stirring and chilling. Dissolved in much cold alcohol and treated with an equal volume of water the ester acid crystallized as buff-colored aggregates of narrow platelets with notched ends, melting and evolving gas at 90–95° and dissolving readily in methyl or ethyl alcohol, especially on warming.

*Analyses.* Calc. for  $C_{16}H_{13}O_6N_3As \cdot 3H_2O$ :  $H_2O$ , 11.31. Found: 11.08.

Calc. for  $C_{16}H_{13}O_6N_3As$ : N, 9.93. Found: 10.18.

**Diazobenzene - (4-arsonic acid) - 3' - amino-6'-methoxybenzoic acid.**—The ester, warmed for one hour in 50% alcohol containing 3 mols. of sodium hydroxide, neutralizing with 1 mol. of acetic acid, and adding alcohol to incipient turbidity, gave the **disodium salt**, which separated from 70% alcohol as rosetts of pale, brownish-yellow, hygroscopic needles.

*Analysis.* Calc. for  $C_{14}H_{12}O_6N_3AsNa_2$ : N, 9.57. Found: 9.67.

The arsonic acid was precipitated in 50% alcohol as rosetts of yellow microscopic needles which decompose at 140° when anhydrous.

*Analyses.* Calc. for  $C_{14}H_{14}O_6N_3As \cdot 1.5H_2O$ :  $H_2O$ , 6.40. Found: 6.47.

Calc. for  $C_{14}H_{14}O_6N_3As$ : N, 10.63. Found: 10.64.

**Diazobenzene - (4-arsonic acid) - 3' - amino-anisic methyl ester.**—Alcoholic B  $\rightarrow$  A + sodium acetate. The ester acid, recrystallized from much 50% alcohol, forms glistening yellow needles which decompose at about 150° with preliminary darkening, and dissolve readily in methyl alcohol.

*Analyses.* Calc. for  $C_{16}H_{13}O_6N_3As \cdot 2.5H_2O$ :  $H_2O$ , 9.91. Found: 9.20.

Calc. for  $C_{16}H_{13}O_6N_3As$ : N, 10.26. Found: 10.37.

**Diazobenzene - (4-arsonic acid) - 3' - amino-anisic acid.**—I. Best prepared by saponification of the ester as described for the isomeric *o*-methoxy derivative. From 70% alcohol the disodium salt forms balls of fine yellow needles. II. The salt was also obtained directly, although in poorer yield, by the reaction of sodium 3-amino-anisate with the neutralized diazo solution and the addition of an equal volume of absolute alcohol.

*Analyses.* Calc. for  $C_{14}H_{12}O_6N_3AsNa_2 \cdot 10H_2O$ :  $H_2O$ , 29.08. Found: I, 30.13; II, 30.36.

Calc. for  $C_{14}H_{12}O_6N_3AsNa_2$ : N, 9.57; As, 17.08. Found: N, I, 9.68; II, 9.69; As, 17.23, 16.92.

The free acid was precipitated from 50% alcohol as aggregates of minute, yellow, microscopic needles which intumesce at 150–5° with preliminary darkening when anhydrous and are difficultly soluble in hot methyl alcohol.

*Analyses.* Calc. for  $C_{14}H_{14}O_6N_3As \cdot 1.5H_2O$ :  $H_2O$ , 6.40. Found: 6.30.

Calc. for  $C_{14}H_{14}O_6N_3As$ : N, 10.63. Found: 10.63.

**Diazobenzene - (4-arsonic acid) - 6' - aminopiperonylic methyl ester.**—B hydrochloride  $\rightarrow$  A, followed by sodium acetate. Reprecipitated from very dilute aqueous ammonia the ester acid forms minute aggregates of short, flat, almost colorless needles which do not decompose below 280° and are practically insoluble in the neutral solvents.

*Analysis.* Calc. for  $C_{16}H_{14}O_7N_3As$ : N, 9.92. Found: 9.91.

On saponification, a sodium salt was easily obtained, which, however, gave poor analytical figures, as did also the acid obtained from it. An attempt to prepare the diazo-amino acid directly from 6-aminopiperonylic acid yielded a dye which was not investigated further.

**Diazobenzene - (4-arsonic acid) - 4' - aminocinnamic ethyl ester.**—3.8 g. of amino ester were diazotized in 60 cc. of *N* hydrochloric acid with chilling and treated with 20 cc.

of *N* sodium hydroxide solution. Without filtering from the yellow precipitate which formed, 4.4 g. of arsanilic acid in 20 cc. of *N* sodium hydroxide solution were added and finally 50 cc. of saturated sodium acetate solution. The initial amorphous precipitate changed to flat, yellow, microscopic needles of the sodium salt, which separates from 70% alcohol as bright yellow microscopic needles which are sparingly soluble in cold water.

*Analyses.* Calc. for  $C_{17}H_{17}O_6N_3AsNa \cdot 6H_2O$ :  $H_2O$ , 19.67. Found: 19.69.

Calc. for  $C_{17}H_{17}O_6N_3AsNa$ : N, 9.52. Found: 10.08.

The arsonic acid forms aggregates of fine, yellow, microscopic needles which decompose at 155–60°.

*Analysis.* Calc. for  $C_{17}H_{15}O_6N_3As$ : N, 10.02; As, 17.89. Found: N, 10.32; As, 17.88.

**Diazobenzene - (4-arsonic acid) - 4' - aminocinnamic acid.**—The ester salt was saponified in 50% alcohol containing 2 mols. of sodium hydroxide, followed by 1 mol. of acetic acid, and then alcohol. Recrystallized from 70% alcohol the disodium salt formed yellow microscopic needles which dissolved readily in water.

*Analyses.* Calc. for  $C_{15}H_{12}O_6N_3AsNa_2 \cdot 6H_2O$ :  $H_2O$ , 19.89. Found: 19.96.

Calc. for  $C_{15}H_{12}O_6N_3AsNa_2$ : N, 9.66; As, 17.23. Found: N, 9.43; As, 16.83.

The acid is precipitated from 50% alcohol as a gelatinous mass which changes to yellow, microscopic needles which decompose at 155–60° with preliminary darkening and sintering when anhydrous, and are appreciably soluble in boiling methyl alcohol.

*Analyses.* Calc. for  $C_{15}H_{14}O_6N_3As \cdot 0.5 H_2O$ :  $H_2O$ , 2.25. Found: 2.11.

Calc. for  $C_{15}H_{14}O_6N_3As$ : N, 10.74. Found: 10.83.

**Diazobenzene - (4-arsonic acid) - 4' - amino-phenylarsonic acid.**—The diazo solution from 4.4 g. of arsanilic acid was treated with 4.4 g. of arsanilic acid in 40 cc. of *N* sodium hydroxide solution. The monosodium salt crystallized on rubbing. From 50% alcohol it forms thin, yellow, lustrous platelets which dissolve appreciably in water.

*Analyses.* Calc. for  $C_{12}H_{12}O_6N_3As_2Na \cdot 2.5H_2O$ :  $H_2O$ , 8.79. Found: 9.47.

Calc. for  $C_{12}H_{12}O_6N_3As_2Na$ : N, 8.99. Found: 9.01.

In 1 mol. of normal sodium hydroxide it yields the disodium salt on addition of sodium acetate, separating from 50% alcohol as woolly masses of delicate yellow needles which dissolve quite readily in water.

*Analyses.* Calc. for  $C_{12}H_{11}O_6N_3As_2Na_2 \cdot 7H_2O$ :  $H_2O$ , 20.49. Found: 20.18.

Calc. for  $C_{12}H_{11}O_6N_3As_2Na_2$ : N, 8.59. Found: 8.61.

The arsonic acid, precipitated from dilute aqueous solution, separates from 95% alcohol as pale yellow aggregates of microscopic needles which intumesce at 154° with preliminary darkening and sintering.

*Analyses.* Calc. for  $C_{12}H_{13}O_6N_3As_2$ : N, 9.44; As, 33.68. Found: N, 9.17; As, 33.84.

#### (D) Diazo-amino Compounds of Arsanilic Acid with Aryl Glycines.

**Diazobenzene - (4-arsonic acid) - phenylglycine.**—Alcoholic B  $\rightarrow$  neutralized A gave a thick slurry of the red-brown monosodium salt. The collected salt was dissolved in 10 parts of 50% alcohol with sodium hydroxide and the filtrate treated with a slight excess of acetic acid, slowly separating as flat, brown-yellow microscopic needles which are sparingly soluble in cold water. The free acid could not be obtained crystalline. The properties of the substance show that it is a true diazo-amino compound, but its color and that of its solutions indicate that it is contaminated with the corresponding azo dye, especially as Mai<sup>6</sup> obtained dyes on using phenylglycine as a coupler in mineral acid solution.

<sup>6</sup> Mai, *Ber.*, 35, 580 (1902).

*Analyses.* Calc. for  $C_{14}H_{18}O_6N_3AsNa \cdot 2H_2O$ :  $H_2O$ , 8.24. Found: 7.21.

Calc. for  $C_{14}H_{18}O_6N_3AsNa$ : N, 10.47; As, 18.70. Found: N, 10.22; As, 18.90.

**Diazobenzene - (4-arsonic acid) - *p* - tolylglycine.**—B + 1 mol. alkali  $\rightarrow$  A + sodium acetate, gave the monosodium salt, which was dissolved in dil. sodium hydroxide solution, treated with saturated sodium acetate solution, and then with an excess of acetic acid. The pure salt crystallized as radiating masses of tan, microscopic needles which are difficultly soluble in cold water.

*Analyses.* Calc. for  $C_{15}H_{18}O_6N_3AsNa \cdot 1.5H_2O$ :  $H_2O$ , 6.11. Found: 6.83.

Calc. for  $C_{15}H_{18}O_6N_3AsNa$ : N, 10.12; As, 18.06. Found: N, 10.07; As, 17.68.

When liberated in 50% alcohol the acid separates as radiating masses of flat, pale terra-cotta-colored microscopic needles which intumesce at  $148-9^\circ$  with preliminary softening and reddening, and are appreciably soluble in alcohol.

*Analysis.* Calc. for  $C_{15}H_{18}O_6N_3As$ : N, 10.69. Found: 10.77.

**Diazobenzene - (4-arsonic acid) - benzylglycine.**—B + mol. alkali  $\rightarrow$  neutralized A followed by hydrochloric acid. The precipitate was dissolved in warm alcohol and water added to incipient turbidity, the arsonic acid separating as an almost colorless, glistening mass of branched and curved microscopic needles and prisms which intumesce at  $155-60^\circ$ . It is readily soluble in methyl alcohol.

*Analyses.* Calc. for  $C_{15}H_{18}O_6N_3As$ : N, 10.68; As, 19.07. Found: N, 10.68; As, 19.05.

**Diazobenzene - (4-arsonic acid) - 4'-methoxy-phenylglycine ethyl ester.**—Alcoholic B  $\rightarrow$  neutralized A + equal volume of alcohol, followed by sodium acetate, gave the sodium salt which separates from 85% alcohol as yellow-brown leaflets and flat needles which are easily soluble in water. The acid could not be obtained crystalline.

*Analyses.* Calc. for  $C_{17}H_{19}O_6N_3AsNa \cdot 4H_2O$ :  $H_2O$ , 13.55. Found: 13.79.

Calc. for  $C_{17}H_{19}O_6N_3AsNa$ : N, 9.15. Found: 9.05.

**Diazobenzene - (4-arsonic acid) - 4'-methoxy-phenylglycine.**—B + 1 mol. alkali  $\rightarrow$  neutralized A, on chilling in a freezing mixture, treating with an excess of acetic acid, and rubbing, gave the monosodium salt as a highly colored powder. Redissolved in dil. sodium hydroxide solution and acidified with acetic acid, it separated as yellow, microscopic platelets which are sparingly soluble in cold water, but dissolve on gentle warming, forming reddish solutions. The acid could not be made to crystallize. The salt was also obtained by saponification of the ethyl ester described above.

*Analyses.* Calc. for  $C_{15}H_{18}O_6N_3AsNa \cdot 2H_2O$ :  $H_2O$ , 7.71. Found: 6.98.

Calc. for  $C_{15}H_{18}O_6N_3AsNa$ : N, 9.74; As, 17.39. Found: N, 9.79; As, 17.16.

**Diazobenzene - (4-arsonic acid) - 4'-ethoxy-phenylglycine ethyl ester.**—Obtained as in the preceding case, the sodium salt separates from 70% alcohol as lustrous, cream-colored leaflets.

*Analyses.* Calc. for  $C_{15}H_{21}O_6N_3AsNa \cdot 2.5H_2O$ :  $H_2O$ , 8.69. Found: 8.78.

Calc. for  $C_{15}H_{21}O_6N_3AsNa$ : N, 8.88. Found: 9.05.

Liberated from 25% alcoholic solution, the acid forms almost colorless microscopic rhombohedra.

**Diazobenzene - (4-arsonic acid) - 4'-ethoxy-phenylglycine.**—On saponifying the ester in 2 mols. of N sodium hydroxide solution at room temperature, adding a little sodium acetate, and then an excess of acetic acid with chilling, the monosodium salt of the glycine arsonic acid crystallized as aggregates of thin, yellow, microscopic needles which are sparingly soluble in water. The free acid could not be obtained crystalline.

*Analyses.* Calc. for  $C_{15}H_{17}O_6N_3AsNa \cdot 2H_2O$ :  $H_2O$ , 7.48. Found: 6.49.

Calc. for  $C_{15}H_{17}O_6N_3AsNa$ : N, 9.44; As, 16.85. Found: N, 9.54; As, 16.63.

This salt was also obtained directly from the diazo solution and *p*-ethoxy-phenylglycine, as in the case of the *p*-methoxy compound.

## (E) Diazo-amino Compounds of the Amino-phenoxyacetic Acids.

**Diazobenzene - (4-arsonic acid) - 4'- amino-phenoxyacetic ethyl ester.**—B hydrochloride  $\rightarrow$  neutralized A, half saturated with sodium acetate, gave the sodium salt which forms brownish aggregates of microscopic needles from 85% alcohol.

*Analyses.* Calc. for  $C_{16}H_{17}O_6N_3AsNa \cdot 5H_2O$ :  $H_2O$ , 16.83. Found: 17.04.

Calc. for  $C_{16}H_{17}O_6N_3AsNa$ : N, 9.44; As, 16.83. Found: N, 9.84; As, 16.99.

Liberated in 50% alcoholic solution, the ester acid forms salmon-colored, minute, glistening leaflets which melt and decompose at  $132-3^\circ$  with preliminary softening and dissolve readily in warm methyl and ethyl alcohols.

*Analysis.* Calc. for  $C_{16}H_{15}O_6N_3As$ : N, 9.93. Found: 9.76.

**Diazobenzene - (4-arsonic acid) - 4'- amino-phenoxyacetic acid.**—Although this substance was prepared directly from *p*-amino-phenoxyacetic acid<sup>7</sup> it was found preferable to saponify the above ester. The ester salt was warmed gently for one hour with 2 mols. of *N* sodium hydroxide solution and an equal volume of alcohol, chilled, neutralized with acetic acid, and the crude disodium salt precipitated with alcohol. It forms brown needles from 85% alcohol which gradually darken and decompose on standing.

*Analyses.* Calc. for  $C_{14}H_{12}O_6N_3AsNa_2 \cdot 6.5H_2O$ :  $H_2O$ , 21.05. Found: 21.35.

Calc. for  $C_{14}H_{12}O_6N_3AsNa_2$ : N, 9.56. As, 17.07. Found: N, 9.58; As, 17.06.

A well chilled solution in 100 parts of water was strongly acidified with acetic acid, causing the sudden incomplete separation of the free arsonic acid as aggregates of microscopic crystals. The cold mixture was just acidified to congo red and filtered cold, for if allowed to warm the acid rapidly dissociates and dissolves. It melts and intumesces at  $132^\circ$ .

*Analysis.* Calc. for  $C_{14}H_{14}O_6N_3As$ : N, 10.64. Found: 10.41.

**Diazobenzene - (4-arsonic acid) - *p* - amino-phenoxyacetamide.**—Aqueous *p*-amino-phenoxyacetamide<sup>8</sup>  $\rightarrow$  neutralized A, half saturated with sodium acetate, gave the sodium salt in excellent yield. It separates from 50% alcohol as rosetts and sheaves of delicate, drab-colored needles which dissolve fairly readily in water.

*Analyses.* Calc. for  $C_{14}H_{14}O_6N_4AsNa \cdot 6H_2O$ :  $H_2O$ , 20.62. Found: 19.88.

Calc. for  $C_{14}H_{14}O_6N_4AsNa$ : N, 13.46; As, 18.02. Found: N, 13.72; As, 17.56.

The arsonic acid, obtained from the salt in 50% alcohol, formed branched aggregates of cream-colored, microscopic needles and hairs which melt and effervesce at about  $162^\circ$  with preliminary browning.

*Analysis.* Calc. for  $C_{14}H_{16}O_6N_4As$ : N, 14.22. Found: 14.09.

**Diazobenzene - (4-arsonic acid) - *p* - amino-phenoxyacet-methylamide.**—The amorphous salt from *p*-amino-phenoxyacet-methylamide<sup>9</sup> soon crystallized, separating from water as pale yellow aggregates of hair-like needles.

*Analyses.* Calc. for  $C_{15}H_{16}O_6N_4AsNa \cdot 4H_2O$ :  $H_2O$ , 14.34. Found: 14.60.

## AROMATIC ARSENIC COMPOUNDS. X. AZO DYES DERIVED FROM ARSANILIC ACID.

BY WALTER A. JACOBS AND MICHAEL HEIDELBERGER.

Received June 29, 1920.

As stated in the previous paper, azo dyes containing arsenic were first described by Ehrlich and Bertheim<sup>1</sup> and later by Barrowcliff, Pyman, and Remfry,<sup>2</sup> and others. In our work with diazo-amino derivatives it was found that certain classes of aromatic amino compounds yielded amino-azo dyes at once when used as couplers with diazotized arsanilic acid, or gave diazo-amino compounds which rapidly rearranged into the dyes. This occurred with *N*-alkyl anthranilic acids, *m*-amino-phenoxyacetic acid and its substitution products, the amino-veratric acids, and the *o*-methyl and *o*-alkoxy derivatives of *N*-phenylglycine.

As far as we can find, no mention has been made of the use of *N*-alkyl-anthranilic acids for the synthesis of azo dyes. The addition of *N*-methyl anthranilic acid to the neutralized diazo solution results in the rapid formation first of the diazo-amino compound, which slowly rearranges to the dye on standing or changes over rapidly on acidification with acetic acid. A similar behavior was noted with *N*-ethyl- and *N*-iso-amyl-anthranilic acids.

Under the usual conditions of coupling in neutral or slightly acid solution, *m*-amino-phenoxyacetic acid yielded at once a dye in which we assume the azo group to enter the position *para* to the amino group. We believe that *m*-amino-phenoxyacetic acid functions here as a *m*-anisidine derivative as we have since noted the analogous experience of Reverdin, Rilliet and Vernei,<sup>3</sup> in which *p*-amino-azo dyes were prepared from *m*-phenetidine. Azo derivatives were also obtained by us from two groups of substitution products of *m*-anisidine and *m*-amino-phenoxyacetic acid, in one of which the position *para* to the amino group was free, and in the other of which this position was occupied by a substituent. In the former group were 4-methyl-5-amino-phenoxyacetic acid and 2-amino-3,4-dimethoxy-benzoic acid, and in these cases the azo group presumably entered the free *para* position. In the second group were 2-methyl-5-amino-phenoxyacetic acid, 3-amino-6-methoxy-phenoxyacetic acid, 6-amino-*o*-veratric acid, 4-amino-6-methoxy-phenoxyacetic acid, and amino-*o*-phenylene-di (oxyacetic acid); and in this group it is probable that the azo group enters the position *ortho* to the amino group. Thus German patent 230,592 describes the formation of *o*-amino-azo dyes

<sup>1</sup> Ehrlich and Bertheim, *Ber.*, 40, 3292 (1907).

<sup>2</sup> Barrowcliff, Pyman and Remfry, *J. Chem. Soc.*, 93, 1893 (1908).

<sup>3</sup> *C. A.*, 13, 312 (1919).

from 2-methyl-5-amino-phenoxyacetic acid and from the analogous 2-methyl-5-amino-anisole, and our experience has confirmed the ready formation of azo dyes from such substances.

Finally, although phenylglycine yields principally a diazo-amino compound under the conditions described in the preceding paper, the *o*-methyl, *o*-methoxy, and *o*-ethoxyphenyl glycines at once form dyes. According to Mai,<sup>4</sup> however, when phenylglycine was coupled in a solution acid to congo red it yielded dyes with diazotized aniline and sulfanilic acid.

In most cases the reaction between the diazotized arsanilic acid and the coupler proceeded smoothly, with very little gas evolution. The isolation and purification of the resulting dyes often presented considerable difficulty, and much experimentation was necessary in order to discover the best conditions for the coupling and whether any dye were best isolated as the free acid, the monosodium salt, or the disodium salt. Hence the manipulative details are quite voluminous, and in order to save space it is deemed best to present the work in abstract form.

The monosodium salts of the dyes were generally very sparingly soluble in water, while the disodium salts dissolved easily. Even very dilute solutions of the latter gave immediate amorphous precipitates with salts of the heavier metals, while their behavior varied toward salts of the alkaline earths.

### Experimental.

To avoid constant repetition it may be stated here that the diazotization of arsanilic acid was carried out under the conditions given in the preceding paper in 2 mols. of normal hydrochloric acid with 5 *N* sodium nitrite. Since most of the amino acids were coupled under the conditions necessary for the formation of the monosodium salts of the resulting dyes, it will be understood unless otherwise stated that the diazo solution was first treated with one mol. of *N* sodium hydroxide solution, the solution thus containing diazobenzene arsonic acid and no free mineral acid. This solution was then slowly treated, with continued turbinizing and chilling, with a solution of the amino acid dissolved in one mol. of *N* sodium hydroxide solution, or treated with an additional mol. of alkali and then with a solution of the coupler hydrochloride in the case of basic couplers. Such a procedure will be indicated by the expression  $B \rightarrow A$ . Cases in which the diazo solution was added to the coupler are designated by  $A \rightarrow B$ . Variations from this procedure will be described as they occur.

The values given for water of crystallization were determined on the substances after they had come to equilibrium in the air.

<sup>4</sup> Mai, *Ber.*, 35, 580 (1902).

**(A) Dyes Derived from Arsanilic Acid and Methoxy-naphthylamines.**

**1-Amino-2-methoxy-naphthalene-4'-azobenzene-4'-arsonic acid.**—**B**  $\longrightarrow$  **A**, using  $\beta$ -methoxy- $\alpha$ -naphthylamine hydrochloride. The neamorphous acid was converted into the salt with just enough dil. sodium hydroxide solution. After salting out, dissolving in 50% alcohol, heating, and making just acid to congo red with hydrochloric acid, the arsonic acid slowly separated on rubbing and cooling as radiating aggregates of narrow, bluish-black, glistening, microscopic platelets, which did not melt below 285°. It dissolves in conc. sulfuric acid with a deep purple color and in dil. sodium hydroxide solution with a deep cherry-red tint.

*Analyses.* Calc. for  $C_{17}H_{16}O_4N_3As \cdot 1.5H_2O$ :  $H_2O$ , 6.3. Found: 5.9.

Calc. for  $C_{17}H_{16}O_4N_3As$ : N, 10.48; As, 18.68. Found: N, 10.42; As, 18.50.

**1-Amino-4-methoxy-naphthalene-2-azobenzene-4'-arsonic acid.**—Obtained like the preceding compound, the arsonic acid separated rapidly as dark brown, microcrystalline aggregates with a bronzy luster. It sintered and darkened when heated, softening to a tar at about 195° and intumescing at about 225°. It dissolves in conc. sulfuric acid with a purplish-red color, changing to brown-red, and becoming purplish again on dilution. In dil. sodium hydroxide solution the color is a deep cherry-red. It is soluble in acetic acid and alcohol.

*Analyses.* Calc. for  $C_{17}H_{16}O_4N_3As \cdot 1.5H_2O$ :  $H_2O$ , 6.3. Found: 6.0.

Calc. for  $C_{17}H_{16}O_4N_3As$ : N, 10.48; As, 18.68. Found: N, 10.31; As, 18.83.

**(B) Dyes Obtained from Arsanilic Acid and Substituted Amino-benzoic Acids.**

**4-Methylamino-5-carboxy-phenylazo-benzene-4'-arsonic acid.**—**B** (methylantranilic acid)  $\longrightarrow$  **A** + equal volume saturated sodium acetate solution. The orange colored solution, which presumably contained the diazo-amino compound, deepened in color on standing, gradually depositing the orange monosodium salt in good yield. Recrystallized from boiling water containing a little sodium acetate, it forms radiating masses of short, brownish-yellow, microscopic needles which dissolve with difficulty in hot or cold water with an intense orange-yellow color.

*Analyses.* Calc. for  $C_{14}H_{13}O_5N_3AsNa \cdot 2.5H_2O$ :  $H_2O$ , 10.08. Found: 10.49.

Calc. for  $C_{14}H_{13}O_5N_3AsNa$ : N, 10.47. Found: 10.53.

Treated in a little water with one mol. of sodium hydroxide, then with alcohol to initial turbidity, the disodium salt separated in the cold. It forms bundles of flat, red, microscopic needles from 70% alcohol and dissolves readily in water with a deep orange color.

*Analyses.* Calc. for  $C_{14}H_{13}O_5N_3AsNa_2 \cdot 8.5H_2O$ :  $H_2O$ , 26.57. Found: 26.63.

Calc. for  $C_{14}H_{13}O_5N_3AsNa_2$ : N, 9.93. Found: N, 9.83.

The monosodium salt, suspended in hot water, dissolved with a little sodium hydroxide, and treated with hydrochloric acid until just acid to congo red, gave the free acid, which when recrystallized from 50% alcohol forms brick-red, thin, glistening microscopic needles and plates. It does not melt below 280° dissolves in conc. sulfuric acid with a deep orange color and gives a red solution in hot 10% hydrochloric acid, from which the hydrochloride separates on cooling as rosetts of narrow, purplish-red plates with a steel-blue reflex. In dil. hydrochloric acid the dye reacts with sodium nitrite, giving a precipitate of pale salmon-colored, microscopic needles, presumably the nitroso compound.

*Analyses.* Calc. for  $C_{14}H_{13}O_5N_3As$ : N, 11.08; As, 19.78. Found: N, 11.24; As, 19.68.

**4-Ethylamino-5-carboxy-phenylazo-benzene-4'-arsonic acid.**—**B**  $\longrightarrow$  **A**.—The crude monosodium salt was dissolved in hot water with a little sodium hydroxide and

the solution just acidified to congo red, yielding the bright yellow arsonic acid. It separates from 85% alcohol as deep orange, glistening rectangular platelets which do not melt below 275°. It is more soluble in methyl alcohol or boiling amyl alcohol than in the other usual neutral solvents, and in its color reactions and chemical properties resembles the methylamino compound.

*Analyses.* Calc. for  $C_{15}H_{15}O_6N_3As$ : N, 10.69; As, 19.06. Found: N, 10.72 As, 19.11.

**4 - Iso-amyl-amino - 5 - carboxy-phenylazo-benzene-4'-arsonic acid.**—B  $\longrightarrow$  A.—The crude monosodium salt when recrystallized from much water containing a little sodium acetate forms orange-colored, microscopic leaflets which are very difficultly soluble in boiling water.

*Analyses.* Calc. for  $C_{15}H_{21}O_6N_3AsNa \cdot 2H_2O$ :  $H_2O$ , 7.31. Found: 6.59.

Calc. for  $C_{15}H_{21}O_6N_3AsNa$ : N, 9.19. Found: 9.18.

Recrystallized from acetic acid, the free acid forms orange-red, glistening, striated platelets which do not melt below 275°. It dissolves in boiling alcohol and gives a deep red-orange color with conc. sulfuric acid; in conc. hydrochloric acid it dissolves with a deep red color, the hydrochloride separating on rubbing as dark colored microscopic needles.

*Analyses.* Calc. for  $C_{15}H_{20}O_6N_3As$ : N, 9.66; As, 17.22. Found: N, 9.48; As, 17.32.

**4 - Amino - 2,3 - dimethoxy-5-carboxy-phenylazo-benzene-4'-arsonic acid.**—B  $\longrightarrow$  A.—Using vicinal aminoveratric acid, the monosodium salt was obtained, separating as flat, brown-orange, microscopic needles from hot water containing a little sodium acetate.

*Analyses.* Calc. for  $C_{15}H_{15}O_7N_3AsNa \cdot 2.5H_2O$ :  $H_2O$ , 9.15. Found: 9.79.

Calc. for  $C_{15}H_{15}O_7N_3AsNa$ : N, 9.40; As, 16.77. Found: N, 9.76; As, 16.54.

The free acid separates from 85% alcohol as long, narrow, glistening, orange-red platelets which turn a deeper red when anhydrous, but do not melt below 275°. It is quite easily soluble in cold methyl alcohol and gives a deep orange-colored solution in conc. sulfuric acid, dissolving in boiling 10% hydrochloric acid with a dark red color, depositing the hydrochloride on cooling as brown platelets and flat needles.

*Analyses.* Calc. for  $C_{15}H_{15}O_7N_3As \cdot 1.5H_2O$ :  $H_2O$ , 5.98. Found: 6.43.

Calc. for  $C_{15}H_{15}O_7N_3As$ : As, 17.62. Found: As, 17.78.

**2 - Amino - 4,5 - dimethoxy-3-carboxy-phenylazo-benzene-4'-arsonic acid.**—(B  $\longrightarrow$  A.—Alkalinity sufficient for formation of the disodium salt.) 6-Amino-*o*-veratric acid<sup>5</sup> was used. After 24 hours about 20% of solid sodium acetate was added and then an excess of acetic acid, precipitating the monosodium salt. Recrystallized from water containing sodium acetate, cautiously adding acetic acid after cooling, the salt forms spherules of orange-red microcrystals which change to chocolate-brown when air-dry. It is very difficultly soluble in boiling water and dissolves on adding alkali with an orange color.

*Analyses.* Calc. for  $C_{15}H_{15}O_7N_3AsNa \cdot 1.5H_2O$ :  $H_2O$ , 5.70. Found: 6.37.

Calc. for  $C_{15}H_{15}O_7N_3AsNa$ : N, 9.40; As, 16.77. Found: N, 9.21; As, 16.65

The free acid separates from an alkaline solution of the salt in 50% alcohol on acidifying to congo red as glistening brown leaflets and microcrystalline aggregates with a purplish luster, containing about 1.5 molecules of water of crystallization and turning darker brown when dehydrated. It decomposes somewhat on heating, but does not melt up to 290°. It is difficultly soluble in the usual solvents, and unlike the monosodium salt, dissolves in dil. alkalis with a red color, only changing to orange at high dilution. It gives an intense red color in conc. sulfuric acid, and dissolves partially in conc. hydro-

<sup>5</sup> This acid was prepared by the following series of reactions, which will be dealt with in a later communication: *o*-vanillin  $\longrightarrow$  *o*-veratric aldehyde  $\longrightarrow$  6-nitro-*o*-veratric aldehyde  $\longrightarrow$  6-nitro-*o*-veratric acid  $\longrightarrow$  6-amino-*o*-veratric acid.

chloric acid, the hydrochloride soon separating as dark orange-red microcrystalline spherules.

*Analyses.* Calc. for  $C_{15}H_{16}O_7N_3As \cdot 1.5H_2O$ :  $H_2O$ , 5.98. Found: 5.29.

Calc. for  $C_{15}H_{16}O_7N_3As$ : N, 9.89. Found: 9.69.

### (C) Dyes Derived from Arsanilic Acid and Aromatic Glycines.

**4-[Phenyl - (4'-arsonic acid) azo] - phenylglycine.**—Although phenylglycine yielded the diazo-amino compound under the conditions given in the preceding paper, the dye was formed in the presence of an excess of mineral acid. The diazo solution from 4.4 g. of arsanilic acid was added, with stirring and chilling, to a solution of 3.1 g. of phenylglycine in 40 cc. of *N* hydrochloric acid diluted to 100 cc. with 0.5 *N* hydrochloric acid. The dye, which crystallized soon after deposition commenced, was filtered off, washed first with cold and then with hot water, and was finally cooled and washed with acetone. The yield was 5.3 g. A dilute solution in 50% alcohol was obtained with the aid of a little ammonia and acidified hot to congo red, the arsonic acid soon separating as orange-red aggregates of minute, lenticular platelets with a golden luster. It sinters, melts, and decomposes slowly at 170–5°, and dissolves in dil. alkali with a reddish-orange color. It dissolves in conc. sulfuric acid or 1 : 1 hydrochloric acid with a deep red color, the hydrochloride separating from the latter on rubbing as red microscopic needles with a purplish luster.

*Analyses.* Calc. for  $C_{14}H_{14}O_5N_3As \cdot 0.5H_2O$ :  $H_2O$ , 2.32. Found: 2.86.

Calc. for  $C_{14}H_{14}O_5N_3As$ : N, 11.07. Found: 11.43.

**2 - Methyl - 4 - [phenyl - (4'-arsonic acid) azo] phenylglycine.**—(A unneutralized  $\rightarrow$  B in 2 mols. of alkali.) The dye salt separated on rubbing and was dissolved in 50% alcohol with the aid of sodium hydroxide and the red-orange solution then made just acid to congo red, the arsonic acid separating as red-brown needles, leaflets, and rhombic platelets. When rapidly heated to 155°, then slowly, the acid reddens and intumesces at 157°. It is quite soluble in the cold in methyl alcohol, and dissolves in conc. sulfuric acid with a deep red color. A solution in 1 : 1 hydrochloric acid deposits the hydrochloride on rubbing as minute, dark brown platelets with a purple luster.

*Analyses.* Calc. for  $C_{15}H_{16}O_5N_3As \cdot H_2O$ :  $H_2O$ , 4.38. Found: 3.49.

Calc. for  $C_{15}H_{16}O_5N_3As$ : N, 10.69; As, 19.06. Found: N, 10.70; As, 19.08.

**2 - Methoxy - 4 - [phenyl - (4'-arsonic acid) azo] phenylglycine.**—(B in 1 mol. of alkali  $\rightarrow$  A treated with one mol. of alkali and saturated with salt.) The monosodium salt gradually crystallized. It separates from dil. aqueous alcoholic alkali on adding acetic acid as very thin, nacreous, orange-red platelets containing about 2.5 molecules of water of crystallization when air-dry and dissolving in water with a deep red color, changing to brown and depositing microcrystalline spherules of what appears to be a different hydrate; on adding sodium acetate or sodium hydroxide a clear, deep orange solution results.

*Analyses.* Calc. for  $C_{15}H_{15}O_6N_3AsNa \cdot 2.5H_2O$ :  $H_2O$ , 9.46. Found: 8.93.

Calc. for  $C_{15}H_{15}O_6N_3AsNa$ : As, 17.39. Found: 17.28.

The acid was obtained in the usual way as minute, glistening, steel-blue aggregates of platelets. When rapidly heated the air-dry acid melts and effervesces at about 160°, but if dried first it gradually reddens on heating and intumesces at 167° to a blood-red mass. It is quite soluble in the cold in methyl alcohol, easily in hot ethyl alcohol, and dissolves in conc. sulfuric acid with a deep purple color, in 1:1 hydrochloric acid with a deep red color, and in dil. solutions of carbonates or alkalis with an orange color.

*Analyses.* Calc. for  $C_{15}H_{16}O_6N_3As \cdot 1.5H_2O$ :  $H_2O$ , 6.19. Found: 6.11.

Calc. for  $C_{15}H_{16}O_6N_3As$ : N, 10.27. Found: N, 10.30°.

**2 - Ethoxy - 4 - [phenyl - (4'-arsonic acid) azo] phenylglycine.**—On adding an equal volume of saturated sodium chloride solution to the turbid reaction mixture

the monosodium salt separated as a paste, but crystallized on rubbing. From 50% alcohol it forms rosetts of orange-brown, glistening platelets which dissolve in water with a brown-red color.

*Analyses.* Calc. for  $C_{16}H_{17}O_6N_3AsNa \cdot 2.5H_2O$ :  $H_2O$ , 9.19. Found: 8.68.

Calc. for  $C_{16}H_{17}O_6N_3AsNa$ : N, 9.44. Found: 9.63.

The free acid separates very incompletely as rosetts and sheaves of flat, purplish-brown, microscopic needles which decompose at  $245-50^\circ$  and are freely soluble in 50% alcohol and 50% acetic acid, especially on warming. The solution in conc. sulfuric acid is deep red, appearing purple in thin layers.

*Analysis.* Calc. for  $C_{16}H_{15}O_6N_3As$ : N, 9.93. Found: 10.12.

$\alpha'$ -[Phenyl - (4'-arsonic acid) azo] -  $\alpha$ -naphthylglycine.—The monosodium salt was precipitated from the reaction mixture with an equal volume of alcohol, converted into the disodium salt by dissolving in one molecular equivalent of sodium hydroxide and adding alcohol until precipitation began, purifying by redissolving in warm 50% alcohol and treating with alcohol until the concentration of solvent was about 85%, whereupon the salt crystallized. It dissolves readily in water with a purple color.

*Analyses.* Calc. for  $C_{18}H_{14}O_6N_3AsNa_2$ : N, 8.88; As, 15.85. Found: N, 9.00; As, 15.36.

The salt was dissolved in 25% alcohol, made just acid to congo red, and filtered at once from a trace of amorphous matter, after which the free acid soon crystallized. It melts and decomposes at about  $275^\circ$  with preliminary darkening and softening and dissolves in conc. sulfuric acid with a deep red color, appearing purple in thin layers.

*Analyses.* Calc. for  $C_{18}H_{14}O_6N_3As \cdot 0.5H_2O$ :  $H_2O$ , 2.1. Found: 3.0.

Calc. for  $C_{18}H_{14}O_6N_3As$ : N, 9.79. Found: 9.48.

#### (D) Dyes Derived from Arsanilic Acid and Aromatic *N*-Methyl Sulfonic Acids.

4 - [Phenyl - (4'-arsonic acid) azo] - phenyl-aminomethyl sulfonic acid,  $H_2O_3AsC_6H_4N:NC_6H_4NHCH_2SO_3H$ .—Methylene-aniline sodium bisulfite solution was added to neutralized A saturated with salt. The disodium salt of the dye soon began to crystallize on keeping in the cold, and the process was hastened by the addition of two-thirds of a volume of saturated sodium acetate solution. Recrystallized from 50% alcohol, the salt separates as delicate, orange-colored needles which dissolve readily in water.

*Analyses.* Calc. for  $C_{18}H_{15}O_6N_3SAsNa_2 \cdot 4.5H_2O$ :  $H_2O$ , 15.01. Found: 15.09.

Calc. for  $C_{18}H_{15}O_6N_3SAsNa_2$ : N, 9.15; As, 16.32. Found: N, 9.63; As, 16.78.

The salt was dissolved in 25% alcohol and the solution acidified to congo red. The acid soon separated as sheaves of minute, flat, red needles with a purplish reflex. It dissolves with difficulty in cold water, readily on boiling, with a red color. When rapidly heated to  $185^\circ$ , then slowly, the anhydrous acid turns bright red, then sinters, and finally swells and melts partially at  $187-9^\circ$ . It dissolves in conc. sulfuric acid with a transient, deep orange color, quickly fading to yellow.

*Analyses.* Calc. for  $C_{18}H_{14}O_6N_3SAs \cdot 2H_2O$ :  $H_2O$ , 7.99. Found: 8.23.

Calc. for  $C_{18}H_{14}O_6N_3SAs$ : N, 10.12; As, 18.05. Found: N, 10.30; As, 18.25.

2 - Methoxy - 4 - [phenyl - (4'-arsonic acid) azo] - phenyl-aminomethyl sulfonic acid.—As in the preceding case, methylene-*o*-anisidine sodium bisulfite yielded a disodium salt which was dissolved in a small volume of water and treated cautiously with somewhat more than an equal volume of alcohol. On standing in the cold, the salt separated as orange-red, microscopic needles dissolving readily in water with a deep orange-red color.

*Analyses.* Calc. for  $C_{14}H_{14}O_7N_3SAsNa_2 \cdot 3H_2O$ :  $H_2O$ , 9.95. Found: 9.96.

Calc. for  $C_{14}H_{14}O_7N_3SAsNa_2$ : As, 15.32. Found: 15.52.

In 50% alcohol, mineral acid causes the free arsonic acid to separate as lustrous, flat, violet needles. The anhydrous acid reddens and softens above 155°, and melts with slow gas evolution at 158–60°, dissolving in conc. sulfuric acid with a deep purple color which changes to deep red on standing.

*Analyses.* Calc. for  $C_{14}H_{16}O_7N_3As \cdot 1.5H_2O$ :  $H_2O$ , 5.72. Found: 4.95.

Calc. for  $C_{14}H_{16}O_7N_3As$ : N, 9.44. Found: 9.28.

### (E) Dyes Derived from Arsanilic Acid and Substituted Phenoxyacetic Acids.

**3 - Amino - 6 - [phenyl - (4'-arsonic acid) azo] - phenoxyacetic acid**,  $H_2O_2AsC_6H_4N:NC_6H_3(NH_2)OCH_2CO_2H$ .—*m*-Amino-phenoxyacetic acid<sup>6</sup> yielded a deep red solution which was gently warmed and treated with alcohol, depositing the orange microcrystalline monosodium salt, which was converted into the acid by dissolving in a considerable volume of dilute alcohol with the aid of sodium hydroxide and making the solution just acid to congo red. The acid separated as red, glistening needles. When anhydrous it blackens, but does not melt below 285°, dissolving in conc. sulfuric acid with an orange-red color, in dil. alkalis with an orange color, and gives an orange-red color in 1:1 hydrochloric acid, the hydrochloride separating on rubbing as orange-brown microscopic crystals.

*Analyses.* Calc. for  $C_{14}H_{14}O_6N_3As \cdot 1.5H_2O$ :  $H_2O$ , 6.40. Found: 6.99.

Calc. for  $C_{14}H_{14}O_6N_3As$ : N, 10.63; As, 18.96. Found: N, 10.74; As, 18.75.

**4 - Methyl - 3 - amino - 6 - [phenyl - (4'-arsonic acid) azo] - phenoxyacetic acid**.—4-Methyl-5-amino phenoxyacetic acid<sup>7</sup> gave the monosodium salt of the dye as a red, crystalline mass which was converted as usual into the acid, this separating as dark red aggregates of flat needles with a purple reflex. When rapidly heated to 240°, then slowly, the dye intumesces at 242–3°, with preliminary blackening. It gives an orange color in conc. sulfuric acid or dil. alkalis, and is difficultly soluble in conc. hydrochloric acid, changing on rubbing to an orange-red, microcrystalline hydrochloride.

*Analyses.* Calc. for  $C_{15}H_{16}O_6N_3As \cdot H_2O$ :  $H_2O$ , 4.22. Found: 3.47.

Calc. for  $C_{15}H_{16}O_6N_3As$ : N, 10.27; As, 18.31. Found: N, 10.06; As, 18.51.

**2 - Methyl - 5 - amino - 4 - [phenyl - (4'-arsonic acid) azo] - phenoxyacetic acid**.—In the case of 2-methyl-5-amino-phenoxyacetic acid,<sup>7</sup> the deep red-brown solution of the monosodium salt was filtered, concentrated partially *in vacuo*, and allowed to stand in the cold. The resulting crystals were dissolved in boiling 85% alcohol containing acetic acid, and on cooling the free acid separated. Reprecipitated in 33% alcohol it forms flat, glistening, purplish-brown needles which dissolve readily in methyl alcohol, less easily in ethyl alcohol. When rapidly heated to 185°, then slowly, it intumesces at 187–8°. It dissolves in conc. sulfuric acid with a deep orange color and partially in conc. hydrochloric acid with a red shade, soon depositing the hydrochloride as dull red microcrystals.

*Analyses.* Calc. for  $C_{15}H_{16}O_6N_3As \cdot 2H_2O$ :  $H_2O$ , 8.09. Found: 7.07.

Calc. for  $C_{15}H_{16}O_6N_3As$ : N, 10.27. Found: 10.38.

**3 - Amino - 6 - methoxy - 4 - [phenyl - (4'-arsonic acid) azo] - phenoxyacetic acid**.—Precipitation of the dye acid obtained from 3-amino-6-methoxy-phenoxyacetic acid<sup>8</sup> was facilitated by the addition of acetic acid and the collected product was dissolved in dil. sodium hydroxide, filtered, and reprecipitated with an excess of acetic acid. Reprecipitated in 50% alcohol, the acid separates as flat, glistening, bronze needles and platelets. The air dry acid sinters, softens, and swells at 175–85°, while the anhydrous substance intumesces at 208–13° with preliminary sintering and softening. It dissolves

<sup>6</sup> THIS JOURNAL, 39, 2912 (1917).

<sup>7</sup> *Ibid.*, 39, 2193 (1917).

<sup>8</sup> *Loc. cit.*, p. 2194.

appreciably in the cold in methyl or ethyl alcohol, readily on warming, and dissolves in dil. alkalis or carbonates with an orange-red color. It gives a bright red color in conc. sulfuric acid and yields a deep purplish-red solution in 1:1 hydrochloric acid, almost immediately depositing the hydrochloride as dark brown, microscopic platelets.

*Analyses.* Calc. for  $C_{15}H_{16}O_7N_3As \cdot 4.5H_2O$ :  $H_2O$ , 16.02. Found: 15.47.

Calc. for  $C_{15}H_{16}O_7N_3As$ : N, 9.88. As, 17.64. Found: N, 9.89; As, 17.62.

**4 - Amino - 6 - methoxy - 3 - [phenyl - (4' - arsonic acid) azo] - phenoxyacetic acid.**—Using 4-amino-6-methoxy-phenoxyacetic acid,<sup>9</sup> the monosodium salt of the dye gradually separated, best on concentrating to smaller bulk *in vacuo* and allowing to stand in the ice box. Recrystallized from dil. sodium acetate solution, it separates as chocolate colored, microscopic needles which are very sparingly soluble in water, but dissolve on adding carbonate or alkali with a dark red color.

*Analyses.* Calc. for  $C_{16}H_{18}O_7N_3AsNa \cdot 6H_2O$ :  $H_2O$ , 20.75. Found: 21.03.

Calc. for  $C_{16}H_{18}O_7N_3AsNa$ : As, 16.77. Found: 16.31.

The free acid can be precipitated in 50% alcohol as minute, glistening, maroon platelets. It does not melt below  $280^\circ$ , and dissolves in conc. sulfuric acid with a bright red color. A solution in hot 1:1 hydrochloric acid deposits the hydrochloride on cooling as dark red, flat needles.

*Analyses.* Calc. for  $C_{16}H_{18}O_7N_3As \cdot 2H_2O$ :  $H_2O$ , 7.81. Found: 7.89.

Calc. for  $C_{16}H_{18}O_7N_3As$ : N, 9.89. Found: 9.97.

**4 - Amino - 5 - [phenyl - (4' - arsonic acid) azo] - 1,2-bis-phenoxyacetic acid.**—A  $\rightarrow$  B, using 4-amino-1,2-bis-phenoxyacetic acid.<sup>10</sup> After acidifying with acetic acid the monosodium salt of the dye separated as dark purplish-brown, microcrystalline spherules. It is very sparingly soluble in water, but dissolves with an orange-red color on adding carbonate or alkali.

*Analyses.* Calc. for  $C_{16}H_{18}O_9N_3AsNa \cdot 4.5H_2O$ :  $H_2O$ , 14.17. Found: 14.40.

Calc. for  $C_{16}H_{18}O_9N_3AsNa$ : N, 8.56. Found: 8.61.

When precipitated in much warm 50% alcohol, deposition of amorphous material is prevented and the free acid separates as dark purplish-brown microcrystals. Its repetition of this process was necessary before the acid was analytically pure. A dissolves in conc. sulfuric acid with an orange-red color, and when anhydrous, softens and sinters when heated, but does not melt below  $280^\circ$ .

*Analyses.* Calc. for  $C_{16}H_{18}O_9N_3As \cdot 3H_2O$ :  $H_2O$ , 10.33. Found: 10.58.

Calc. for  $C_{16}H_{18}O_9N_3As$ : N, 8.96. As, 15.97. Found: N, 9.07; As, 15.8.

**$\alpha$  - Amino -  $\beta$  - [phenyl - (4-arsonic acid)] azo -  $\alpha'$  - naphthoxyacetic acid.**— $\alpha$ -Amino- $\alpha'$ -naphthoxyacetic acid<sup>11</sup> gave a deep purple, amorphous precipitate which was dissolved by adding 1 mol. of sodium hydroxide and the solution treated with several volumes of alcohol, causing deposition of the disodium salt. Recrystallized from 50% alcohol, it separates as dark brown, felted microscopic needles which dissolve readily in water with a dark purplish-red color.

*Analyses.* Calc. for  $C_{18}H_{14}O_6N_2AsNa_2 \cdot 9H_2O$ :  $H_2O$ , 24.89. Found: 25.25.

Calc. for  $C_{18}H_{14}O_6N_2AsNa_2$ : N, 8.59; As, 15.33. Found: N, 8.46; As, 15.71.

The free acid may be precipitated in much warm 50% alcohol as flat, dark red needles with a golden luster. It decomposes at about  $285^\circ$ , with preliminary darkening and softening. It dissolves in conc. sulfuric acid with a deep purplish-red color.

*Analysis.* Calc. for  $C_{18}H_{16}O_6N_2As$ : N, 9.44. Found: 9.47.

**$\alpha$  - Amino -  $\alpha'$  - [phenyl - (4-arsonic acid)] azo -  $\beta$  - naphthoxyacetic acid.**—Sodium salt of  $\alpha$ -amino- $\beta$ -naphthoxyacetic acid  $\rightarrow$  neutralized A. The deep purple solution was concentrated to small bulk *in vacuo* and treated with several volumes of alcohol.

<sup>9</sup> *Loc. cit.*, p. 2212.

<sup>10</sup> *Ibid.*, p. 2216.

<sup>11</sup> *Ibid.*, p. 2217.

the disodium salt separating in the cold. Recrystallized from 50% alcohol it forms almost black aggregates of microscopic hairs with a greenish reflex and dissolving in water with a deep red color.

*Analyses.* Calc. for  $C_{13}H_{14}O_6N_3AsNa_2 \cdot 8.5H_2O$ :  $H_2O$ , 23.84. Found: 23.64.

Calc. for  $C_{13}H_{14}O_6N_3AsNa_2$ : N, 8.59; As, 15.33. Found: N, 8.56; As, 15.81.

The free acid, when liberated in much 50% alcohol slowly separates as red-brown microcrystalline aggregates which do not melt below  $285^\circ$ .

*Analyses.* Calc. for  $C_{13}H_{16}O_6N_3As \cdot H_2O$ :  $H_2O$ , 3.89. Found: 3.96.

## CHROMO-ISOMERIC SILVER SALTS OF PENTABROMOPHENOL AND A THEORY OF CHROMO-ISOMERISM OF SOLID COMPOUNDS.

BY HOWARD J. LUCAS AND ARCHIE R. KEMP.

Received March 4, 1921.

### 1. Previous Investigations.

Two silver salts of pentabromophenol have been described. Bodroux<sup>1</sup> obtained a rose-colored amorphous precipitate upon adding silver nitrate to a solution of the potassium salt. Hantzsch and Scholtze<sup>2</sup> also obtained a reddish amorphous precipitate in the same manner, ascribing the color to an impurity present in the pentabromophenol; but they also described a colorless, amorphous form, which precipitates when alcoholic silver nitrate is added to an alcoholic solution of the ammonium salt, and they apparently regard it as a purer lot of the same salt, which they describe as colorless, and existing in only one form. Isomeric silver salts of other

<sup>1</sup> Bodroux, *Compt. rend.*, 126, 1282-85 (1898).

<sup>2</sup> Hantzsch and Scholtze, *Ber.*, 40, 4882 (1907).

phenols are described by Hantzsch and Scholtze,<sup>2</sup> by Torrey and Hunter,<sup>3</sup> and by Hunter and Joyce.<sup>4</sup>

## 2. Outline of This Investigation.

In the work described in this article, in order to eliminate the possibility of the color being due to impurities, the pentabromophenol was carefully purified by repeated crystallizations from alcohol and by boiling with animal charcoal until a colorless product was obtained and the melting point of successive crops did not change.

The determination of silver in the various salts was carried out by the cyanide-sulfide method as described by Lucas and Kemp.<sup>5</sup> The accuracy of this method was demonstrated in the case of the salt of the formula  $C_6Br_5OAg$ , which is stable and can be obtained in a high degree of purity. This salt was prepared by heating the yellow crystalline ammoniate of the formula  $C_6Br_5OAg \cdot 2NH_3$ . The formula  $C_6Br_5OAg$  requires 18.11% of silver. Three analyses gave 18.10%, 18.12%, and 18.12%—results which show that the method is highly accurate.

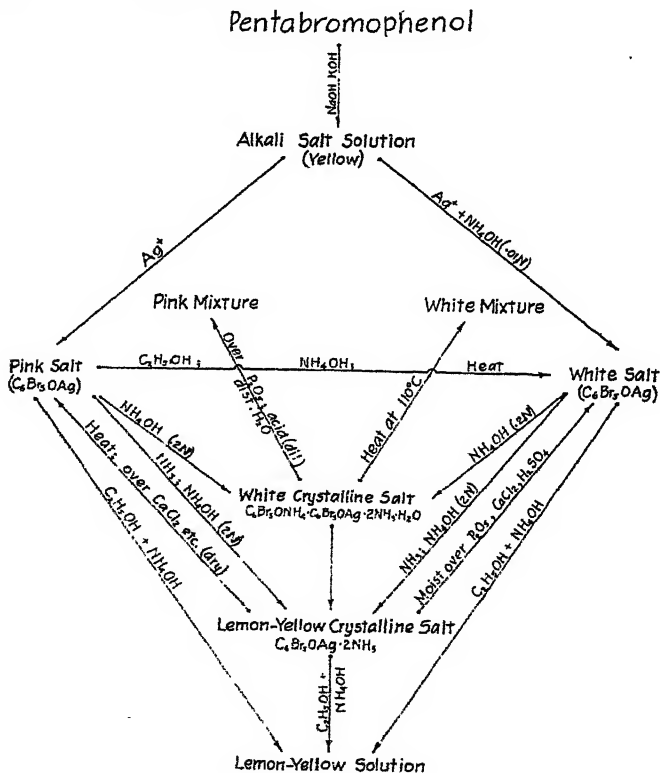

Fig. 1.

<sup>4</sup> Hunter and Joyce, *THIS JOURNAL*, 39, 2640 (1917).

<sup>5</sup> Lucas and Kemp, *ibid.*, 39, 2074 (1917).

When pentabromophenol is treated with a solution of sodium hydroxide it dissolves, and the solution has a yellow color. The color is intensified on heating, but fades again on cooling. Diluting the solution causes a gradual fading out of the color. The sodium salt of pentabromophenol crystallizes from this yellow aqueous solution in colorless featherlike needles. The color of the solution is not due to impurities; for it persists after repeated crystallizations of the white pentabromophenol.

The pink silver salt separates when silver nitrate solution is added to the sodium pentabromophenolate solution; but, if the silver nitrate is 0.01 *N* in ammonium hydroxide, the colorless form precipitates. The concentration of ammonia must not be much greater, because at about 0.2 *N* another salt, consisting of an ammoniate, separates—a colorless shimmering crystalline compound, which has a satiny appearance as it moves through the liquid. If the concentration of ammonia is still greater, another ammoniate which can be obtained in well-defined yellow needles, separates after standing.

The accompanying chart shows the relationships between the phenol, the colored and colorless silver salts, and the two ammoniates.

### 3. Discussion of the Color Relations and a New Theory of Chromoisomerism.

It seems unreasonable to ascribe the color of the solution of the sodium salt to tautomerism of the benzoid-quinoid type, because it must then be assumed that sodium is linked to carbon. Compounds in which sodium is known to be joined to carbon are decomposed by water with formation of sodium hydroxide. Thus the carbides of sodium and potassium<sup>6</sup> react vigorously with water, and so does sodium phenyl,<sup>7</sup> forming sodium hydroxide and benzene. The fact that the colorless salt gives rise to a colored solution must therefore be ascribed either to some other structural change or electronic condition. Now, since in solution the sodium salt is largely ionized, it is clear that the difference in color must be due to some difference in the powers of absorbing light possessed by the ion and by the un-ionized molecule. According to present views, however, the absorption of light is caused by the vibration of electrons, and this must increase with the looseness with which the electrons are bound and with the corresponding tendency of the compound to undergo structural changes or shifting of the valence bonds. Now the production of the anion is accompanied by the formation of a powerful negative electrostatic field, which decreases the effective attraction of the carbon atoms for the electrons; and the latter, being under less restraint, vibrate in

<sup>6</sup> Matignon, *Compt. rend.*, **125**, 1033-5 (1897).

<sup>7</sup> Acree, *Am. Chem. J.*, **29**, 590 (1903).

longer periods. The ion absorbs in the visible violet, and the solution is yellow. This greater vibration may well correspond to an oscillation of the double and single valences between the carbon atoms of the benzene ring. It is known in general that the introduction of halogen into the benzene nucleus causes a shifting of the absorption bands towards the red,<sup>8</sup> and that the addition of a strong base to solutions of phenols also causes a shifting of the absorption bands towards the red.<sup>9</sup>

When an ionized substance passes from solution into the solid state, either of two conditions may result, according to the theory of chromo-isomerism here presented.

(1) As has been shown by the recent X-ray work on the structure of crystals, the atoms or atom-groups that form the ions in solution, such as the sodium and chlorine atoms in sodium chloride, maintain in most crystalline substances their separate identities and probably still carry the same charges that they do in aqueous solution. It is evident, however, that the powerful electrostatic fields which accompany the atoms in the ionized condition will be weaker in the crystalline state; for, instead of existing in the solution more or less independently of other ions, each atom is now surrounded by atoms carrying charges of opposite sign. The intensity of vibration of the electrons will therefore be less and the frequency of vibration shorter, so that the absorption will be displaced toward the violet end of the spectrum, and the crystalline substance may become of a paler red or yellow color than that of its ions in solution, or it may even become colorless.

(2) The compound which first crystallizes from solution may be an unstable form, changing to a more stable form under favorable conditions. Whenever such a transition takes place energy is lost from the system. This means that the rearrangement is due to the tendency of the atoms and atom-groups to assume the position in which the electrostatic fields about them are most completely neutralized. Either the ions may still retain their identities in the more stable packing, or they may become chemically united, in other words as intimately associated as the atoms within the atom-group that constituted the ion in solution. Whatever the actual condition, the weakening of the electrostatic fields strengthens the attraction between atoms and electrons, and the latter now vibrate in still shorter periods, so that absorption of light is displaced farther towards the violet. A solid substance which was still colored in the unstable form, will become less highly colored or even colorless in the stable form; in other words, a change in the electrostatic environment of the absorbing atoms or atom groups brings about

<sup>8</sup> Baly, *J. Chem. Soc.*, 99, 856 (1911); Purvis, *ibid.*, 99, 825 (1911); 107, 966 (1915).

<sup>9</sup> Ewbank, *ibid.*, 87, 1347 (1905); Baly, Tuck and Marsden, *ibid.*, 97, 582 (1910); Wright, *ibid.*, 100, 676 (1900).

a corresponding change in the wave length of the light absorbed, and the wave length is longest when the electrostatic fields are the strongest.

The fact that the solid sodium salt of pentabromophenol is colorless while its anion is yellow may be attributed to either of these conditions. But the existence of two solid silver salts, one of which is pink and the other white, requires for its explanation both assumptions. The facts in regard to these silver salts and their bearing upon this explanation may therefore be more fully considered. They may be briefly summarized as follows.

The analyses of the salts show that they have the same percentage composition. The pink salt is the more reactive. Thus, when the freshly precipitated moist salts are covered with about 20 cc. of alcohol-free ether and 5 cc. of ethyl iodide is added, both give the same product, pentabromophenyl ethyl ether, but the reaction takes place more rapidly with the pink salt. Its color fades slowly, and it is largely changed to silver iodide within one-half hour; whereas the white salt under the same conditions is not completely converted during a much longer time. When put in an atmosphere containing ammonia both salts finally give the same ammonia addition product, but the rate of ammonia absorption by the pink form is more rapid.

All these facts are simply accounted for by the hypothesis that the pink salt is the unstable, more reactive form, and that the white salt is the stable, less reactive form.

That the pink salt is unstable is shown by the ease with which transformation to the colorless form takes place. When the pink form is brought into solution, even to a very slight extent, as may be done by heating it in contact with water or by the addition of a small amount of alcohol or ammonia, the white form results. Thus the color of the pink salt may be ascribed to the same factor as that which gives the color to the solution of the sodium salt, namely, to a strong electrostatic field about the pentabromophenolate ion; while in the white salt the ions have taken up the positions in which their electrostatic fields are most completely neutralized. Thus also the pink salt results when precipitation takes place so rapidly that there is not time for the ions to arrange themselves in the final, more intimate, association characteristic of the more stable white salt.

The color of the yellow ammoniate of silver pentabromophenolate can be readily accounted for on the basis of this theory, since the electrostatic environment is modified by the association of two molecules of the polar compound ammonia with each silver atom, an increase in the strength of the electrostatic fields resulting.

The production of color in the cases mentioned above, *viz.*, the aqueous

solution of the sodium salt, the pink silver salt, and the yellow silver ammoniate, is ascribed to the vibration of the electrons between the carbon atoms of the benzene ring. If such is actually the case, then we should expect visible light to be absorbed by the same mechanism in the case of complex benzene derivatives, particularly when they are in strong electrostatic fields.

The theory that chromo-isomerism in solid salts may arise not only from a difference in molecular structure, but from a difference in crystal structure, when this produces a variation in the strength of the electrostatic field which is associated with the atoms or atom groups of the compound, is applicable to inorganic compounds. For example, the cubic modification of mercuric sulfide is black, the trigonal is red; the cubic modification of thallous iodide is deep red, the rhombic is yellowish-green; the tetragonal modification of mercuric iodide is red, the rhombic is yellow; the trigonal modification of antimony tri-iodide is red, the rhombic is yellowish-green, and the monoclinic is greenish-yellow. It will be noted that the more symmetrical crystal form has the darker color. This seems to justify the conclusion that whenever a compound exists in two or more colored forms, the crystal structure of the darker colored one possesses the greater symmetry. Moreover, the study of crystal structure by means of X-rays indicates that compounds in which the union is entirely polar have the most symmetrical structure and that the presence of more or less firmly bound groups of atoms, *i. e.*, radicals, usually leads to a less symmetrical crystal structure. For example, rock salt crystallizes in the cubic system and calcite in the trigonal. It is probable that greater symmetry goes with a more polar condition, and therefore with greater freedom of vibration owing to the presence of more free charges. It is not surprising, then to find that the deeper colored form of a compound possesses the greater symmetry.

That a difference in crystal structure may account for the different colors of the so-called chromo-isomeric salts of organic acids is shown in the case of thallous picrate. Red thallous picrate is monoclinic, and yellow thallous picrate is triclinic. On the basis of the theory presented, the picrate ion is absorbing light of longer wave length in the former case, because the electrostatic field surrounding it is stronger than in the yellow modification.

When dealing with solutions of colored compounds, it is observed that here also the wave length of the light absorbed varies with the electrostatic environment, in general being greatest in the polar, and least in the non-polar solvents. Thus the head of the absorption band of 4-nitro-*o*-xylene lies closer to the red in alcoholic than in petroleum ether solution, and in the case of nitroquinol dimethyl ether the absorption band progressively shifts to the red in the following solvents in the order

named: light petroleum ether, benzene, alcohol, chloroform, pyridine, water, aniline and conc. sulfuric acid.<sup>10</sup>

Finally, on the basis of this theory, it is not necessary to assume a different structural formula for each differently colored modification of a compound. The whole field of the relationship between color and constitution could be much clarified by applying the principles discussed above.

#### 4. The Experimental Work.

The pentabromophenol used in this work was prepared by the method of Bodroux,<sup>11</sup> which consists in treating phenol with bromine in the presence of anhydrous aluminum bromide. The crude product was treated with cold 95% alcohol to extract the aluminum bromide and lower halogenated products. It was dissolved in hot alcohol, boiled with refined bone charcoal, and allowed to cool slowly, when it crystallized in long needles. This operation was repeated several times, yielding a snow-white product, melting at 229.5° (corr).

The pink silver pentabromophenolate.—A solution of the sodium salt was made by dissolving the phenol in an equivalent quantity of sodium hydroxide in solution which was practically free from chlorides. The solution thus prepared was yellow, and alkaline to litmus. It was diluted until about 0.01 *N*; then a slight excess of 0.05 *N* silver nitrate was added slowly with stirring. The precipitate was brown, due to the presence of silver oxide, but changed to pink on the addition of 0.01 *N* acetic acid until the liquid showed a slight acid reaction with litmus. The precipitate was filtered, the solid removed from the filter and shaken up with much water, filtered again, and after washing thoroughly to remove impurities, sucked as dry as possible. It was placed on a watch glass, allowed to dry for one day in a clean cupboard, then pulverized, spread out thin on a watch glass, and dried over phosphorus pentoxide for several days *in vacuo*. The product was analyzed for silver by the cyanide-sulfide method.<sup>5</sup>

##### ANALYSES.

III.....	0.4734	0.0975	17.93	18.11

The pink salt was also prepared by heating the yellow ammoniate for several hours at 120°.

##### ANALYSES.

Sample.	Wt. of sample. G.	Wt. of Ag <sub>2</sub> S. G.	Ag. found. %.	Ag. calc. from C <sub>6</sub> Br <sub>5</sub> OAg %.
I.....	0.3457	0.0781	18.10	18.11
II.....	0.4492	0.0935	18.12	18.11
III.....	0.2806	0.0584	18.12	18.11

When prepared by the latter method it is much purer than by precipitation, because the yellow ammoniate can be obtained very pure.

The pink salt is insoluble in water, alcohol, ether, ligroin, benzene, carbon tetrachloride, bromobenzene, etc. It dissolves in alcohol to which a little ammonium hydroxide has been added, yielding a deep lemon-yellow solution. With ethyl iodide the dry salt

<sup>10</sup> Baly, Tuck and Marsden, *loc. cit.*; Baly and Rice, *J. Chem. Soc.*, 101, 1478 (1912).

<sup>11</sup> Bodroux, *Compt. rend.*, 126, 1282-5 (1898).

seems to decompose in a manner analogous to the catalytic decomposition first observed by Torrey and Hunter<sup>3</sup> in the case of silver tribromophenolate, and later studied by other investigators.<sup>12</sup> The insoluble pink silver pentabromophenolate first becomes green, then black, and finally yellow; the liquid is not colored during the course of the reaction. No effort was made to study this reaction further. When the moist freshly precipitated salt is covered with about 20 cc. of ether and 4 to 5 cc. of ethyl iodide, the pink color slowly fades until after about one-half hour the solid appears to be entirely silver iodide. If the ether layer is filtered, the solid thoroughly extracted with ether and the solvent allowed to evaporate, pentabromophenyl ethyl ether separates in long slender needles, melting<sup>13</sup> at 131° to 134° (corr.), and after one crystallization from alcohol at 134° to 135° (cor.). From 1.3 g. of the phenol there was obtained 1.1 g. of the ether, a yield of 80%.

The moist pink silver salt is converted into the more stable colorless form on heating, also in the presence of a small amount of alcohol or ammonia. If treated with stronger aqueous ammonia the white ammoniate forms, which goes over into the yellow ammoniate when warmed with strong ammonia solutions. These transformations can be carried out either in the presence or absence of excess silver ion.

**The White Silver Pentabromophenolate.**—This may be prepared from the pink salt, as described above, or directly by the addition of 0.05 *N* silver nitrate solution to the 0.01 *N* solution of the sodium salt made 0.01 *N* with respect to ammonia. The product after washing and drying is a very light cream color.

Sample.	ANALYSES.

IV.....	0.2544	0.0523	17.91	18.11
V.....	0.2118	0.0439	18.06	18.11

The white salt closely resembles the pink in being insoluble in the solvents named above, and dissolving in alcohol containing ammonium hydroxide to form a lemon-yellow solution. It also decomposes with dry ethyl iodide. The moist salt reacts slowly with a solution of ethyl iodide in ether to form the pentabromophenyl ethyl ether. The freshly precipitated white silver salt from 1.8 g. of pentabromophenol was covered with a solution of ethyl iodide in ether, but the rate of reaction was so slow that there was no noticeable change in the color of the solid during an hour, in marked contrast to the more rapid reaction of the pink salt. After standing for 12 hours, there was obtained 1.4 g. of white solid melting at 132–4° (corr.), which was recrystallized from alcohol in the form of long, slender needles that melted at 134–5° (corr.). The yield of pentabromophenyl ethyl ether was about 70%.

In contact with ammonium hydroxide of about 0.2 *N* the silver salt goes over into the white crystalline ammoniate, which dissolves in more concentrated ammonia on heating. From this solution the yellow ammoniate crystallizes if the dilution is not too great.

**The White Crystalline Ammoniate.**—This is formed from either the pink or white salt, as described above, or directly from silver nitrate and the sodium salt, if the concentration of ammonia in the solution is 0.2 *N* or greater. It has a beautiful satiny appearance, reflecting light much as does precipitated mercurous chloride. Under the

microscope the small particles appear as very thin plates, which revolve rapidly as they migrate through the solution.

The salt was filtered and washed with dil. ammonium hydroxide and dried in desiccators containing a small amount of ammonia, one desiccator having sodium hydroxide, and another a mixture of hydrated and anhydrous sodium sulfate as drying agents. That the moist solid has an appreciable vapor pressure of ammonia is shown by the fact that when washed with water or dil. acids, or when dried over phosphorus pentoxide *in vacuo* it turns pink. The dried products from both desiccators retained their crystalline appearance, and were apparently stable upon exposure to air. Analysis for silver and for bromine (by Carius' method) gave the following results, which show the presence of 10 atoms of bromine to one of silver.

Instead of determining the silver bromide, which was mixed with broken glass, the silver contained in it was determined by the cyanide-sulfide method, and the percentage of bromine calculated from the weight of silver sulfide.

Loss on heating was determined by heating 0.6825 g. of the salt dried over sodium hydroxide at 120° to constant weight of 0.6395 g. The loss was 0.0430 g., or 6.30%. Calculated as 3 molecules of ammonia and 1 molecule of water from C<sub>12</sub>H<sub>12</sub>O<sub>2</sub>N<sub>3</sub>Br<sub>10</sub>Ag, the calculated loss is 5.98.

Some of the pink product obtained by drying the white ammoniate over phosphorus pentoxide was analyzed for silver.

## ANALYSES.

Sample.	Wt. of sample. G.	Wt. of Ag <sub>2</sub> S. G.	Ag. found. %.	Ag. calc. from C <sub>12</sub> H <sub>12</sub> O <sub>2</sub> Br <sub>10</sub> Ag. %.
I.....	0.3515	0.0401	9.93	9.95
II.....	0.2938	0.0335	9.93	9.95

These results indicate that 3 molecules of ammonia and 1 of water were lost from C<sub>12</sub>H<sub>12</sub>O<sub>2</sub>N<sub>3</sub>Br<sub>10</sub>Ag.

Ammonium pentabromophenolate is stable over phosphorus pentoxide and when heated to 110° loses ammonia to give a snow-white residue of the pure phenol.

When boiled with alcohol the white crystalline salt leaves a residue of white silver pentabromophenolate and a filtrate containing pentabromophenol in solution, the two approximately equal in amount. If dilute sodium hydroxide is used the same decomposition is observed, except that the phenol is now dissolved as the sodium salt.

From the above data it appears that the white crystalline ammoniate is a double salt of the formula  $C_6Br_5ONH_4.C_6Br_5OAg.2NH_3.H_2O$ , and that it is easily decomposed according to the equation

The silver salt resulting from this decomposition is pink or white, depending upon the conditions.

**The Lemon-yellow Ammoniate of Silver Pentabromophenolate.**—This may be obtained from the salts already described, but is best prepared directly from the solution of the sodium salt by first making it 2 *N* in ammonia and then adding an excess of silver nitrate. The white crystalline salt which first separates is dissolved by warming the solution, which is filtered and the filtrate allowed to stand several hours, when long lemon-yellow needles crystallize. They are filtered with suction, washed in strong ammonia solution, and dried over sodium hydroxide in a desiccator containing a little ammonium chloride. The crystals upon drying retain their color and crystalline structure. The dry salt loses ammonia very slowly at ordinary temperatures, but when heated at 100° to 110° the decomposition is rapid and the pink form of the silver salt remains. This is a deeper red than when formed by precipitation. The yellow salt dissolves in alcohol containing ammonia to give the characteristic lemon-yellow solution (see Fig. 1).

Sample.	ANALYSES.			
	Wt. of sample. G.	Wt. of Ag <sub>2</sub> S. G.	2Ag. found. %.	Ag. calc. from $C_6Br_5OAg.2NH_3$ . %.
I.....	0.2907	0.0570	17.07	17.10
II.....	0.2715	0.0532	17.06	17.10
III.....	0.2470	0.0487	17.17	17.10

When 1.249 g. was heated at 110° to constant weight it lost 0.0684 g., corresponding to 5.46%; the percentage of ammonia calculated from  $C_6Br_5OAg.2NH_3$  is 5.40.

**Absorption of Ammonia by Silver Pentabromophenolate.**—Under the proper conditions the two forms of this salt absorb ammonia to form the yellow ammoniate. But when the vapor pressure of ammonia above the salts is low, only partial absorption takes place, and at different rates for the two salts. Samples of the two salts were weighed out on watch glasses and placed in the same desiccator containing sodium hydroxide and a small amount of ammonium chloride. The salts were taken out at intervals and weighed.

Time elapsed. hours.	Percentage of $NH_3$ .	
	Pink salt. %.	White salt. %.
3	4.96	0.70
6.5	4.96	0.88
22	4.96	1.29
27.5	4.96	1.29

After the salts would no longer absorb ammonia at room temperature, the desiccator was placed in an ice-chest beside the ice. After remaining for 3 hours the salts were again weighed but no change was found. The salts were then transferred to a desiccator containing a much higher partial pressure of ammonia and allowed to stand for 36 hours at room temperature with the result that the percentage of ammonia in the

pink salt increased from 4.96 to the theoretical percentage (5.40%) while that in the white increased from 1.29% to 5.01%. After standing for 4 days in the same desiccator, the percentage of ammonia in the white increased to 5.09%.

The above data show that the absorption of ammonia by the white salt is very much slower than by the pink form. This cannot be due to a difference in the physical state, as the white salt was light and fluffy while the pink was very compact. The total absorption of ammonia by both salts seems to depend upon the partial pressure of the ammonia in the desiccator.

**Other Salts of Pentabromophenol.**—Various salts were prepared by adding neutral solutions of metallic salts to a dilute solution of the sodium salt of pentabromophenol. The following is a list of the positive ions which form difficultly soluble salts with pentabromophenol.

Salts. Colored, not distinctly crystalline.		Salts. White, not distinctly crystalline.		White crystalline salts.	
Ions.	Color.	Ions.		Ions.	
$\text{Cu}^+$	light brown	$\text{Ba}^{++}$		$\text{K}^+$	
$\text{Cu}^{++a}$	red	$\text{Cd}^{++}$		$\text{NH}_4^+$	
$\text{Co}^{++}$	light pink	$\text{Ca}^{++}$		$\text{Li}^+$	
$\text{Fe}^{+++}$	brown	$\text{Ni}^{++d}$		$\text{Mg}^{++}$	
$\text{Fe}^{++}$	yellow	$\text{Mn}^{++}$		....

$\text{Hg}^{+b}$	orange	$\text{Tl}^+$		....	
$\text{Hg}^{++}$	yellow	....		....	

<sup>a</sup> Dissolves in warm 6 *N* ammonium hydroxide which, upon cooling, deposits dark brown needles.

<sup>b</sup> Changes to a perfectly colorless salt upon standing exposed to sunlight.

<sup>c</sup> Changes to a deep violet salt upon standing exposed to sunlight. The violet precipitate dissolves in warm 6 *N* ammonium hydroxide from which lemon-yellow needles separate upon cooling.

<sup>d</sup> Dissolves in warm 6 *N* ammonium hydroxide from which light green needles deposit upon cooling.

## 5. Summary.

1. The silver salt of pentabromophenol exists in two forms, one pink, the other colorless; and in both forms silver is joined to oxygen.

2. Two ammoniates of silver pentabromophenolate are described, one a yellow salt,  $\text{C}_{65}\text{BrOAg} \cdot 2\text{NH}_3$ , and the other a double salt of the formula  $\text{C}_6\text{Br}_5\text{ONH}_4 \cdot \text{C}_6\text{Br}_5\text{OAg} \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$ .

3. A new theory of chromo-isomerism is proposed, on the basis of which the wave length of the light absorbed by a substance will change as the electrostatic environment of the absorbing atoms or atom-groups changes, and will be longest when the electrostatic fields are the strongest.

4. The theory satisfactorily accounts for the yellow color of aqueous solutions of the colorless sodium pentabromophenolate, for the color of the two forms of the silver salt, and for the yellow color of the ammonia addition compound of the latter.

5. Absorption of light in these cases is ascribed to the isorropesis of the benzene ring. It is undoubtedly a factor in color production in the case of other benzene derivatives.

6. The theory satisfactorily accounts for the different colors of polymorphic forms of inorganic compounds, such as mercuric iodide, thallos iodide, etc. The more symmetrical form is the darker colored, because the electrostatic fields about the atoms are stronger in the more symmetrical forms.

7. According to the theory presented, it is not necessary to assign a different formula to each colored modification of a compound. The entire field of color and constitution should be re-examined on the basis of this theory.

In conclusion, the assistance and valuable criticism of Dr. Arthur A. Noyes and Dr. Roscoe G. Dickinson in connection with the development of the theory are gratefully acknowledged.

## ADDITION REACTIONS OF PHOSPHORUS HALIDES. II. THE 1,4-ADDITION OF PHOSPHENYL CHLORIDE.

BY JAMES B. CONANT AND S. M. POLLACK.

Received March 17, 1921.

### I. Introduction.

Phosphorus trichloride readily combines with the carbonyl group of aldehydes<sup>1</sup> and with the conjugated system of  $\alpha,\beta$  unsaturated ketones.<sup>2</sup> This combination involves the formation of a ring containing as one of its members a pentavalent phosphorus atom.

The reaction is reversible and the product cannot be isolated, but may be transformed by suitable reagents into a stable phosphonic acid or its derivative.

These addition reactions are analogous to the formation of the pentahalides by the addition of chlorine or bromine to phosphorus trichloride. The trivalent phosphorus atom is unsaturated, as shown by its combination with the halogens, the carbonyl group or the ends of a conjugated system in unsaturated ketones. The organic derivatives of phosphorus trichloride (the chloro-phosphines) are also unsaturated since they readily unite with two atoms of chlorine. It is, therefore, to be expected that they will combine with certain unsaturated organic substances in a manner completely parallel to phosphorus trichloride itself. Michaelis, in fact, in his exhaustive study of these compounds showed<sup>3</sup> that benzaldehyde combined

<sup>1</sup> THIS JOURNAL, 42, 2337 (1920).

<sup>2</sup> *Ibid.*, 39, 2679 (1917); 42, 830 (1920).

<sup>3</sup> Michaelis, *Ann.*, 293, 193 (1896).

with dichloro-phenylphosphine (phosphenyl chloride) and he was able to isolate a phosphonic acid by treatment of the addition product with water. This is obviously a case of addition to the carbonyl group.

The results here presented show that phosphenyl chloride combines with the ends of the conjugated system of benzal-acetophenone. As in the case of the trichloride an intermediate cyclic compound is first formed.

This readily reacts with acetic acid producing acetyl chloride and a keto-phosphonic acid (I). The chlorine atoms of the addition compound, like those of  $\text{C}_6\text{H}_5\text{PCl}_4$ , are more reactive than those in phosphenyl chloride. As a result phosphenyl chloride and benzal-acetophenone, when mixed with acetic acid, form the keto-phosphonic acid almost quantitatively; the equilibrium of the primary reversible reaction is shifted by the rapid reaction of the addition product with acetic acid.

The proof of the structure of the intermediate cyclic compound rests on the structure of a cyclic anhydride (II) obtained by the action of acetic anhydride. Here again the addition product is more reactive than phosphenyl chloride and the reaction goes to completion in the presence of acetic anhydride.

The cyclic anhydride (II) could be isolated only as an impure gum, but its structure is clearly established by its reactions. On treatment with water it yields the phosphonic acid (I). It combines with two atoms of bromine, thus showing that it is unsaturated. The resulting dibromide (III) on treatment with water forms hydrobromic acid and two isomeric  $\beta$ -bromoketo-phosphonic acids (IV) which are identical with the substances made by the bromination of the keto-phosphonic acid (I).

The bromo acid contains two asymmetric carbon atoms, and thus two

racemic stereo-isomers are possible; both were formed by the bromination of the keto-phosphonic acid, and also by the action of water on the cyclic dibromide. This evidence seems to establish clearly the structure of the anhydride and in turn that of the addition product. Thus, the phosphorus atom in phosphenyl chloride like that in the trichloride,<sup>2</sup> adds to the 1,4 position of the conjugated system.

The two isomeric bromine compounds are stereo-isomers and not structural isomers since they are both decomposed by alkaline reagents with the formation of benzal-acetophenone. This reaction is parallel to the behavior of the  $\beta$ -bromo acid previously studied<sup>2</sup> and establishes the fact that the bromine atom is in the  $\beta$  position. The low-melting isomer may be transformed into the high-melting one by the prolonged action of sunlight on its chloroform solution.

It is interesting to note that the two isomers decompose in aqueous sodium carbonate at appreciably different rates, and both seem to be somewhat more stable in this regard than the  $\beta$ -bromo acid obtained in the work with phosphorus trichloride. It seems possible that this reaction may involve the intermediate formation of a  $\beta$ -phostone (analogous to a  $\beta$ -lactone) which then easily decomposes in the presence of water to form the unsaturated ketone, and the corresponding acid of phosphorus.

Many  $\beta$ -lactones easily lose carbon dioxide with the production of unsaturated compounds, which is a reaction analogous to that shown above.

## II. Experimental.

$\alpha$ -Phenyl- $\beta$ -benzoyl-ethyl-phenylphosphonic Acid,  $\text{C}_6\text{H}_5\text{CH}(\text{C}_6\text{H}_5\text{POOH})\text{CH}_2\text{CO}-\text{C}_6\text{H}_5$ .—Ten g. of benzal-acetophenone was dissolved in a mixture of 9 g. of phosphenyl chloride and 15 g. of glacial acetic acid. The ketone went quickly into solution, which in the course of a few minutes began to become warm and deposit a white crystalline material; the presence of acetyl chloride could be recognized by its odor. The mixture was cooled with running water and after considerable solid had separated 70 cc. of glacial acetic acid was added with stirring. At the end of 30 minutes the mixture was poured into water and the solid filtered off, washed with ethyl alcohol and dried. 19 g. was thus obtained; this is slightly more than the calculated amount. The crude product thus obtained can be best purified by dissolving in sodium carbonate, extracting with ether and reprecipitating with acid. It is very insoluble in all solvents but may be recrystallized from its very dilute solutions in hot glacial acetic acid or ethyl alcohol. It melts with decomposition at  $220^\circ$  to  $225^\circ$ .

*Analysis.* Calc. for  $\text{C}_{21}\text{H}_{19}\text{O}_3\text{P}$ : P, 8.9. Found: 8.7.

Titration with standard sodium hydroxide solution using phenolphthalein as an indicator, showed the compound to be a monobasic acid.

$\alpha$ -Phenyl- $\beta$ -bromo- $\beta$ -benzoyl-ethyl-phenylphosphonic Acid,  $\text{C}_6\text{H}_5\text{CH}(\text{C}_6\text{H}_5\text{POOH})-$

$\text{CHBrCOC}_6\text{H}_5$ .—The phosphonic acid was so insoluble that it could be brominated only in glacial acetic acid. Five g. of the crude acid was brominated with 2.7 g. of bromine by the following procedure. The acid was suspended in 20 cc. of glacial acetic acid and the mixture heated to the boiling point. A small portion of the bromine was added and the heating continued until the color disappeared (about 5 minutes). The bromine was then added slowly and the temperature kept a little below the boiling point of the acetic acid. The reaction proceeded rapidly after it had once started and hydrogen bromide was given off freely. The solid went into solution as the reaction continued, and at the end a clear colorless solution resulted. This was poured into 500 cc. of water, and the solid filtered off and dried. It weighed 6.5 g. and had a melting point of  $160^\circ$  to  $180^\circ$ . This mixture of stereo-isomeric bromine compounds could be separated only with difficulty, as much decomposition took place on heating them in any solvent, particularly methyl and ethyl alcohols. The separation was best effected by treating with 50 cc. of hot chloroform, filtering off the insoluble compound and evaporating the chloroform solution to a volume of 20 cc. On the addition of petroleum ether the low-melting isomer slowly crystallized. 2 g. of substance melting at  $150^\circ$  was thus obtained. The insoluble material was recrystallized from ethyl alcohol; 1 g. of substance melting at  $195^\circ$  was obtained. Recrystallization from the same solvent did not change the melting point.

*High-melting isomer*.—This substance melted with decomposition at  $195^\circ$ . It is very insoluble in all solvents.

*Analysis*. Calc. for  $\text{C}_{21}\text{H}_{18}\text{O}_3\text{PBr}$ : Br, 18.7. Found: 18.6.

*Low-melting isomer*.—This substance melted at  $150^\circ$ ; it is fairly soluble in methyl and ethyl alcohols and very soluble in chloroform. It is only sparingly soluble in petroleum ether.

*Analysis*. Calc. for  $\text{C}_{22}\text{H}_{18}\text{O}_4\text{PBr}$ : Br, 18.7. Found: 19.1.

Both isomers dissolve in aqueous sodium carbonate—although the high-melting isomer only slowly (probably because of its extreme insolubility). When treated with sodium hydroxide solution both substances dissolve and are almost immediately decomposed with the formation of benzal-acetophenone which separates as a precipitate. This same decomposition takes place more slowly in sodium carbonate solution. A dilute sodium carbonate solution of the low-melting isomer became milky after standing for 5 minutes at room temperature. In a parallel experiment with the high-melting substance the solution reached the same degree of opalescence after standing for about 40 minutes. An increase in temperature greatly facilitates this decomposition.

A chloroform solution of the isomer melting at  $149^\circ$  was made faintly red with a trace of iodine and exposed to sunlight. The high-melting isomer very slowly separated, and after many weeks over half of the material had been transformed. The product was identified by a mixed-melting-point determination with the pure substance melting at  $195^\circ$ .

### Reaction in Acetic Anhydride.

The reaction between benzal-acetophenone, phosphenyl chloride, and acetic anhydride is much slower than the corresponding reaction with acetic acid. After evaporating the acetyl chloride formed, the reaction product is left as a gum which is soluble in chloroform. All attempts to obtain a solid substance failed. The reactions of the material, however, show that an unsaturated cyclic anhydride is present at this point. The transformations may be carried out with a chloroform solution of the gum, or with the original reaction mixture somewhat diluted with more acetic anhydride. A typical experiment with each procedure is as follows.

(a) Five g. of benzal-acetophenone, 3.8 g. of acetic anhydride and 4.5 g. of phosphenyl chloride were mixed and allowed to stand for one hour at room temperature and then for 3 hours at 40°. The acetyl chloride and excess of acetic anhydride were evaporated under diminished pressure at a temperature of 40° to 50°. The resulting gum was dissolved in 30 cc. of chloroform. Ten cc. of this solution was treated with 1 cc. of water and enough ethyl alcohol to make a homogeneous solution. Crystals of the phosphonic acid soon began to separate. After 4 hours the precipitate was filtered off; weight 1.7 g., or 61%.

The remaining 20 cc. of solution was treated with 2.9 g. of bromine which it decolorized without evolution of hydrogen bromide. The solution was then treated with 2 cc. of water and 30 cc. of alcohol. After 48 hours the solid was filtered off; 2.7 g. of mixed bromides, m. p. 160° to 170°, was obtained.

(b) Five g. of benzal-acetophenone, 4.5 g. of phosphenyl chloride and 3.5 g. of acetic anhydride were allowed to react as in (a), except that the mixture stood overnight. The solution was diluted to 25 cc. with acetic anhydride. Five cc. of this solution was poured into water; a white precipitate resulted. It was separated, dissolved in sodium hydroxide solution and reprecipitated with acid; 1.6 g. of phosphonic acid, m. p. 220° to 225°, was thus obtained. This was a yield of 94%.

The remaining 20 cc. of solution was treated with 3.9 g. of bromine which was readily taken up, producing only a faint red color at the very end of the addition. The solution was poured into 500 cc. of water; a crystalline precipitate formed which was filtered off; 7 g. of mixed bromides was thus obtained, a yield of 85%. This mixture was separated in the same way as described in the account of the preparation of the bromo acids from the phosphonic acid; 3.3 g. of the low-melting isomer was obtained which melted at 149°. A mixed-melting-point determination showed that it was identical with the low-melting isomer prepared by the bromination of the keto-phosphonic acid. Only about 0.5 g. of high-melting isomer was obtained in the pure condition after recrystallization. Its identity was also established by a mixed-melting-point determination.

### Summary.

1. Benzal-acetophenone reacts with phosphenyl chloride in glacial acetic acid producing a keto-phosphonic acid and acetyl chloride.

2. In acetic anhydride solution the product is an unsaturated cyclic anhydride which readily reacts with water forming the keto-phosphonic acid.

3. The structure of this anhydride follows from the fact that it combines with one equivalent of bromine and the product with water gives two stereo-isomeric  $\beta$ -bromoketo-phosphonic acids. These  $\beta$ -bromo acids were also prepared by bromination of the keto-phosphonic acid.

4. Both  $\beta$ -bromo acids decompose in the presence of aqueous alkali to give benzal-acetophenone, hydrogen bromide and phenylphosphonic acid. This proves they are stereo-isomeric and are  $\beta$ -bromo compounds.

5. The structure of the compound formed in acetic anhydride shows that the first step in the process is the 1,4 addition to the conjugated system of the phosphorus atom of the phosphenyl chloride.

## A REACTION BETWEEN METHYL ALCOHOL AND WATER AND SOME RELATED REACTIONS.

By J. A. CHRISTIANSEN.

Received March 19, 1921.

In experiments on the synthesis of methyl alcohol I had observed that a mixture of steam and methyl alcohol vapor when passed through finely divided reduced copper reacts with the formation of hydrogen and carbon dioxide. To follow up this interesting reaction, I made some further experiments showing that the reaction

proceeds sensibly without side-reactions.

The reduced copper was made from copper oxide precipitated from a hot solution of copper sulfate by means of sodium hydroxide, and was contained in a vertical U-tube (of combustion glass about 20 cm. in height and 10 mm. in diameter, that could be heated in an oil-bath to about 300°. The upper end of one branch was bent in an angle of about 45°, while the upper end of the other was bent to a horizontal position.

From a buret a mixture of methyl alcohol and water was passed through the inclined tube. The velocity of the stream was regulated by a capillary through which it was forced by means of an air pressure of several centimeters of mercury. The horizontal tube was connected with a vertical cooling coil which served to condense the vapors of water, methyl alcohol, and other condensable compounds that passed over. The condensate was collected in a small suction flask with side-tube. From this the gases passed to two spiral absorption tubes containing sodium hydroxide to absorb the carbon dioxide. The non-absorbed gases were finally collected over water in a calibrated gas buret of 500 cc. capacity.

Between the suction flask and the absorption tubes a T-form stopcock was inserted, the free end of which dipped under water in a cylinder. By means of this device it was possible to sweep out the air of the suction flask, and to start and stop the collection of the gases at any given moment. Simultaneously the height of the liquid in the buret was noted, and so the quantity of alcohol solution, delivered during the period, was known.

In each experiment the quantities of carbon dioxide and formic acid (plus methyl formate) were determined by titration, the former according to Winckler's method. The mixture in the gas buret was analyzed by means of an Orsat apparatus.

As the air in the suction flask was displaced by the carbon dioxide-hydrogen mixture before the beginning of the experiment, the volume of hydrogen formed was found by subtracting the volume of diluted

alcohol used from the volume of gas collected, subject to a correction because the air was not totally displaced, and determined by the difference between the air found by analysis and the known volume of the air space in the absorption tubes. This was applied by subtracting  $\frac{1}{4}$  of the difference from the volume of hydrogen found. Of course all volumes were properly corrected for the influence of varying temperature, pressure and moisture content.

Only traces of free acid and carbon monoxide were found.

From these data the molecular proportion between the hydrogen and carbon dioxide formed during the reaction was calculated. In the first experiments this proportion was constantly found at about 2.8, but it appeared that the deviation was due to a piece of rubber tubing, several centimeters in length, inserted between the last absorption coil and the gas buret, through which the hydrogen diffused in spite of the fact that it was completely immersed in water. When this tubing was replaced by a glass tube, the proportion became exactly 3, indicating that the reaction proceeds practically without side reactions according to Equation 1.

The following is a typical experiment.

The alcohol (about 99%) was diluted 1 to 10 by volume. The temperature of the oil-bath was  $255^{\circ} \pm 1^{\circ}$ . During 108 minutes 20.00 cc. of the liquid passed the apparatus.

	Cc.
Volume of gas collected, reduced to standard conditions, dry,	283.6
Correction for distillate	17.7
Correction for air displaced by CO <sub>2</sub>	0.7

Volume of hydrogen found 265.2

CO <sub>2</sub> found	
In 20 cc. of distillate	4.0
In the second absorption tube	1.1
In the first absorption tube	82.5
In gas (?)	0.5

Volume of carbon dioxide 88.1

Volume of hydrogen / Volume of carbon dioxide 3.01

Later it was found that formaldehyde also is hydrolyzed according to the analogous reaction

at a temperature of about  $235^{\circ}$  and with finely divided copper as a catalyst, but the experiments were of a more qualitative nature.

It is very probable that some of the hydrogen is used up in reduction of formaldehyde to methyl alcohol, so that the proportion of hydrogen to carbon dioxide will be smaller than 2, a result also indicated by the above experiments.

In this connection it may be of interest to note that the well known reaction

catalyzed by copper, according to an experiment of mine also proceeds with formation of an excess of carbon dioxide, presumably on account of reduction of formic acid.<sup>1</sup>

### Summary.

Experiments are reported showing that the reactions  $\text{CH}_3\text{OH} + \text{H}_2\text{O} = \text{CO}_2 + 3\text{H}_2$  and  $\text{CH}_2\text{O} + \text{H}_2\text{O} = \text{CO}_2 + 2\text{H}_2$  proceed when suitable vapor mixtures are led through finely divided reduced copper at temperatures about 230° to 250°.

## PREPARATION AND HYDROLYSIS OF BENZYL ESTERS.

By E. H. VOLWILER AND E. B. VLIET.

Received March 24, 1921.

In his classical researches on the therapeutic properties of combined opium alkaloids, and particularly of the alkaloids of the papaverine group, Macht<sup>1</sup> found that the antispasmodic effect of these compounds is due to the benzyl nucleus. This discovery was followed by his investigation of two simple organic esters of benzyl alcohol, namely, benzyl acetate and benzyl benzoate. It was found that the former is undesirable due to gastric disturbances which it induces, whereas benzyl benzoate is quite effective in relaxing unstripped muscle, and is better tolerated than benzyl acetate.

Up to the present time benzyl benzoate is the only benzyl ester which has come into extended use, although benzyl stearate and benzyl succinate have recently been introduced. The chief obstacle in studying new benzyl esters is the difficulty of determining the relative merits of the various esters by any methods that are rapid and fairly accurate. The general insolubility of the esters in water makes pharmacological tests difficult. Hence, in determining the comparative values of new benzyl esters, actual clinical use has always been necessary in spite of the length of time and of the uncertainties incident to such examinations.

A rapid chemical method of gaining a preliminary idea of the value of these esters would be extremely desirable. In devising such a test, it would be necessary to know whether the effect of benzyl esters is due to the entire benzyl ester molecule or to benzyl alcohol formed by hydrolysis of the ester in the body. The fact that benzyl benzoate and benzyl

<sup>1</sup> Cf. Sabatier, "Die Katalyse in der organischen Chemie," Leipzig, 1914, p. 151.

<sup>1</sup> Macht, *J. Pharmacol.*, 9, 287 (1917); 11, 389-446 (1918).

acetate are excreted as hippuric acid and that benzyl alcohol itself has a relaxing effect on unstripped muscle<sup>2</sup> seems to indicate that the effect is due, to some extent at least, to the hydrolysis of the esters. If it develops that the action is due to the benzyl alcohol split off in the body by hydrolysis, it is very probable that the therapeutic effects would be proportional to the rates of hydrolysis of the esters. On the other hand, if the effect is due to the intact benzyl ester molecule, the esters that are more slowly hydrolyzed in the body would probably have the more pronounced action.<sup>3</sup>

We have, therefore, determined the rates of hydrolysis of a number of benzyl esters in dil. alcoholic potassium hydroxide solution. A comparison of these data with the corresponding pharmacological and clinical tests should go far towards indicating the basis on which the therapeutic action of these compounds rests.

The benzyl esters investigated were the benzoate, acetate, cinnamate, salicylate, *p*-aminobenzoate, stearate, fumarate, succinate and acetyl-salicylate.

#### Preparation of the Esters.

Good grades of commercial benzyl benzoate (boiling at 222 to 225°, at 40 mm.) and benzyl acetate (boiling at 210 to 213°, at 745 mm.) were used. Benzyl stearate (melting at 40 to 42°) was furnished by Eli Lilly and Company and benzyl succinate (melting at 41 to 43.5°) by Frederick Stearns and Company.

Benzyl fumarate was prepared from fumaric acid and benzyl alcohol by the method of Bischoff and Hedenström<sup>4</sup> and purified by recrystallizing twice from alcohol. A product was obtained boiling at 210 to 211° at 5 mm. and melting at 58.5 to 59.5°.

Benzyl salicylate<sup>5</sup> was prepared by heating sodium salicylate with a slight excess of benzyl chloride and a small amount of diethylamine in an oil-bath at 130 to 140° for 17 hours. Upon cooling, the mixture was washed with water, the excess of benzyl chloride was removed by steam distillation and the remaining oil was distilled in a vacuum. Practically the entire amount came over between 165° and 192° at 7 mm. Upon redistilling, a yield of 85% of a product boiling at 170 to 175° at 7 mm. was obtained. In this reaction a temperature higher than 140° causes the formation of high-boiling side products while the absence of diethylamine as a catalyst greatly decreases the yield.

<sup>2</sup> Macht, *J. Pharmacol.*, **11**, 263 (1918).

<sup>3</sup> Pharmacological tests on these esters have been carried out in the Department of Pharmacology, of the Abbott Laboratories and published. Nielsen and Higgins, *J. Lab. Clin. Med.*, **6**, No. 7, April (1921); **6**, No. 12, Sept. (1921).

<sup>4</sup> Bischoff and Hedenström, *Ber.*, **35**, 4089 (1902).

<sup>5</sup> Aktien Gesellschaft, *Friedlaender.*, **6**, 1108; (Ger. pat. 119, 463); Gomberg and Buchler, *THIS JOURNAL*, **42**, 2065 (1920).

Benzyl cinnamate<sup>6</sup> was prepared in a manner similar to that for benzyl and after purification by repeated fractional distillation in a vacuum salicylate product was obtained which boiled at 228 to 230° at 22 mm. and crystallized as a white solid melting at 33 to 34°.

Benzyl acetylsalicylate was prepared by heating a mixture of 50 g. of benzyl salicylate, 30 g. of acetic anhydride and 10 g. of finely pulverized anhydrous sodium acetate on a boiling-water bath for 2 hours. The mixture was then cooled, taken up in benzene, washed with dil. sodium hydroxide solution and water; and after drying with calcium chloride the benzene was distilled, leaving a very viscous liquid. This was placed out of doors overnight at a temperature of about 20° whereupon it solidified. The material was purified by dissolving in hot ligroin from which, upon cooling, triturating and inoculating, 40 g. of a white solid was obtained melting at 25 to 25.5°. A portion of this was recrystallized several times from petroleum ether containing a little carbon tetrachloride and a product was obtained melting at 25.5 to 26°. The product is extremely soluble in benzene, xylene, carbon tetrachloride, acetone and ethyl acetate but is only slightly soluble in cold petroleum ether and ligroin. It boils at 197 to 200° at 7 mm.

Subs., 0.1347: CO<sub>2</sub>, 0.3505; H<sub>2</sub>O, 0.0644. Calc. for C<sub>18</sub>H<sub>14</sub>O<sub>4</sub>: C, 71.08; H, 5.22. Found: C, 70.96; H, 5.35.

Benzyl-*p*-aminobenzoate was prepared from benzyl *p*-nitrobenzoate. The nitro ester was prepared by heating 50 g. of sodium *p*-nitrobenzoate, 50 g. of benzyl chloride and 2 cc. of diethylamine in an oil-bath at 130° for 24 hours. Upon cooling, the mixture was taken up in water and benzene. The residue obtained from the benzene layer was freed from benzyl chloride by steam distillation and further purified by two crystallizations from 95% alcohol. An 85% yield of a product melting at 82 to 83° was thus obtained.

The nitro ester was reduced with iron and hydrochloric acid. After two crystallizations from carbon tetrachloride, the solid material had only a faintly yellow tinge and melted at 88.5° to 89.5°. From 42 g. of nitro ester, 25.5 g. of purified benzyl *p*-aminobenzoate was obtained.

Calc. for C<sub>14</sub>H<sub>13</sub>O<sub>2</sub>N: N, 6.17. Found (Kjeldahl): 5.89.

The hydrochloride was prepared by treating an ether solution of the purified base with alcoholic hydrochloric acid. This gave a beautiful white solid melting at 188 to 189° with the formation of some gas.

Shonle and Row<sup>7</sup> give the melting point of the hydrochloride as 1 and state "the free base is a yellow viscous liquid having no definite melting point and becoming wax-like on standing."

### Hydrolysis.

The velocity of saponification of the esters was determined by a method similar to that used by Bischoff and Hedenström.<sup>8</sup> A definite amount of ester was dissolved in 20 cc. of acetone, and 50 cc. of 0.0633 *N* potassium hydroxide solution in 97% alcohol was added, the temperature being kept at 20°. At regular intervals 5-cc. portions were pipetted from the mixture and the excess of potassium hydroxide was titrated with 0.02 *N* hydrochloric acid, using phenolphthalein as indicator. The ratio of the number of moles of ester to the number of moles of potassium hydroxide varied according to the nature of the ester. With esters of dibasic acids, such as fumaric and succinic, two moles of potassium hydroxide were used to one mole of ester while the ratio with esters of mono-basic acids (benzoic, acetic, etc.) was 1:1.

Benzyl salicylate was treated in a slightly different manner, because of the acidic hydroxyl group which holds one mole of potassium hydroxide as long as an excess of alkali is present. Therefore, potassium hydroxide approximately twice as concentrated as that used in the other tests was employed for the salicylate and that for the benzyl acetylsalicylate was about three times as concentrated. A run was made with acetylsalicylic acid in order to determine the rate of hydrolysis of the acetyl group alone, so that the velocity of saponification of the benzyl group in benzyl acetylsalicylate could be estimated.

An attempt was made to determine the rate of saponification of benzyl *p*-aminobenzoate but this proved to be impossible by the method used because the amino group in the free acid is strongly basic, while the amino group in the ester is practically neutral. Hence, the same amount of hydrochloric acid was required to neutralize the mixture, regardless of the extent to which the hydrolysis had proceeded. That hydrolysis had actually occurred was evidenced by the fact that during the first few hours a precipitate was obtained when the alcohol-acetone reaction mixture was diluted with water, whereas after 24 hours, no precipitate formed under these conditions.

Duplicate runs were made in nearly all cases, which indicate that the results are accurate within about 3%. The results are shown by the accompanying curves.

The irregularity of the curve for benzyl stearate is perhaps due to the fact that a precipitate of potassium stearate separated from the reaction mixture after hydrolysis had proceeded for about 3 hours. This would tend to decrease the concentration of the reaction products and allow the hydrolysis to proceed more rapidly. A check run showed close agreement at all points. No precipitate formed from any of the other esters.

The result for benzyl acetylsalicylate is calculated so that if both the

<sup>8</sup> Bischoff and Hedenström, *Ber.*, 35, 3433 (1902).

acetyl and benzyl groups were completely hydrolyzed, the result would be 200%. The difference between these values and those for acetylsalicylic acid alone should give the velocity of hydrolysis of the benzyl group,

assuming that the rate of hydrolysis of the acetyl group is the same for both compounds. This seems to be true, for the difference is approximately equal to the rate of hydrolysis of the benzyl group in benzyl salicylate.

### Summary.

1. The comparative rates of hydrolysis of benzyl benzoate, acetate, cinnamate, salicylate, stearate, fumarate, succinate and acetylsalicylate were determined in order to obtain a basis for the correlation of chemical properties and physiological action.

2. The rates of hydrolysis of these benzyl esters increase in the following order: salicylate, benzoate, stearate, cinnamate, acetate, succinate and fumarate.

3. The results indicate that the rate of hydrolysis of the benzyl group in benzyl acetylsalicylate is of the same order as in benzyl salicylate.

# ADDITION REACTIONS OF PHOSPHORUS HALIDES. III. THE REACTION WITH DIBENZAL-ACETONE AND CINNAMYLIDENE-ACETOPHENONE.

BY JAMES B. CONANT, ALBERT H. BUMP AND HAROLD S. HOLT.

Received April 4, 1921.

Both phosphorus trichloride and phosphenyl chloride (phenyl-dichlorophosphine) readily combine with the conjugated system of simple unsaturated ketones such as benzal-acetophenone. The addition product reacts with glacial acetic acid and forms a saturated keto-phosphonic acid.<sup>1</sup> As a continuation of the study of these reagents on conjugated systems, two di-olefenic ketones—dibenzal-acetone and cinnamylidene acetophenone—have been investigated. Keto-phosphonic acids were obtained by the action of phosphorus trichloride on both substances but the yields were unsatisfactory. Phosphenyl chloride gave much better results; the yields were fairly good and the acids obtained were high melting, crystalline substances. This reagent, therefore, seems to be a promising one for the further investigation of unsaturated ketones.

Both reagents combine with only one of the two conjugated systems in dibenzal-acetone; it was not possible to obtain diphosphonic acids such as might be formed by the addition of a second molecule of the reagent. The addition to cinnamylidene-acetophenone takes place in the 1,4 position although there is the possibility of 1,6 addition with this compound. This is in agreement with the results obtained by adding other reagents to this same substance.

## The Reaction with Dibenzal-acetone.

The reaction between this ketone and the phosphorus halide was carried out in glacial acetic acid; no attempt was made to isolate any intermediate products, as the mechanism of the reaction has already been established. A dibasic keto-phosphonic acid (I) was obtained by the use of the trichloride and a monobasic acid (II) by the use of phosphenyl chloride.

Both of these substances are unsaturated; they combine with two atoms of bromine and are readily oxidized with the formation of benzaldehyde. This establishes their structure. The monobasic acid (II) when oxidized with ozone yielded, besides benzaldehyde, a dibasic acid of the formula  $\text{C}_6\text{H}_5\text{CH}(\text{C}_6\text{H}_5\text{PO}_2\text{H})\text{CH}_2\text{COOH}$ . The first decomposition product of the

<sup>1</sup> THIS JOURNAL, 42, 830 (1920).

ozonide, an  $\alpha$ -ketonic aldehyde, could not be isolated, and under the conditions of the experiment, was apparently transformed into the saturated acid with one less carbon atom.

The dibromides which were formed from both acids (I) and (II), very readily lost hydrobromic acid when treated with alkaline reagents and formed unsaturated monobromo acids. The structure of these monobromides is as shown below (III and IV).

This structure is in accord with the well-known ease with which  $\beta$ -bromo ketones lose hydrobromic acid when treated with alkaline reagents.

The only other possibility is that the dibromide is not a real addition product but is formed by the substitution of one of the hydrogens of the  $\text{CH}_2$  group and subsequent addition of hydrobromic acid to the double bond. This hydrobromic acid would then be readily removed by alkaline reagents and the monobromides would have the structures represented by (V) and (VI).

In view of the somewhat unusual behavior of these monobromides with alkaline reagents, it was necessary to decide definitely between these alternative formulas. This was accomplished by oxidation with ozone. The dibasic monobromide (III or V) yields a tribasic acid,  $\text{C}_6\text{H}_5\text{CH}(\text{PO}_3\text{H}_2)\text{CH}_2\text{COCO}_2\text{H}$ ; on heating, it is transformed into a substance the analysis of which is in agreement with the formula  $\text{C}_6\text{H}_5\text{CH}(\text{PO}_3\text{H}_2)\text{CH}_2\text{CO}_2\text{H}$ . Such acids could result only by the oxidation of a compound represented by Formula III; a substance with the alternative structure (V) would yield an  $\alpha$ -bromo acid. Furthermore, the first decomposition product of the ozonide of a substance of Structure III should be an acid bromide. This could not be isolated but its presence was shown by the fact that hydrobromic acid was formed when the ozonized solution was shaken with cold water.

In the case of the other monobromo acid (IV or VI), hydrobromic acid was formed as before, but the ketonic acid could not be isolated. Its decomposition product  $\text{C}_6\text{H}_5\text{CH}(\text{C}_6\text{H}_5\text{PO}_2\text{H})\text{CH}_2\text{COOH}$ , however, was obtained and found to be identical with the acid formed by oxidation of the

keto-phosphonic acid (II). This establishes the structure of the monobromide as being that represented by Formula IV. The addition of bromine to the unsaturated acids thus proceeds normally.

### Reactions of the Monobromides.

Certain  $\beta$ -bromophosphonic acids which have been previously described<sup>1</sup> are very unstable in the presence of aqueous alkaline reagents. For example, the bromo acid prepared from benzal-acetophenone is decomposed even by sodium hydrogen carbonate solution forming the unsaturated ketone, sodium bromide and sodium phosphate.

It was therefore of interest to investigate the action of alkaline reagents on the bromides prepared in this research. The dibromide dissolves in cold sodium hydrogen carbonate or carbonate solution without decomposition. On warming these solutions, however, decomposition takes place, the odor of benzaldehyde becoming at once apparent. Both dibromides can be transformed into monobromides as previously stated. This is accomplished by the use of one equivalent of potassium hydroxide, or better by an excess of potassium acetate.

The monobromo acids readily dissolve in sodium carbonate solution without decomposition. Aqueous potassium hydroxide solutions of the acids, however, decompose quite rapidly with the formation of benzaldehyde and the removal of bromine and the phosphorus radical. No other definite products could be isolated with the monobasic acid (IV). In the case of the dibasic acid (III), however, a small amount of dibenzalacetone was formed. The use of alcoholic potassium hydroxide solution increased the yield of unsaturated ketone to 25%. This formation of the unsaturated ketone is most surprising. No evidence for the mechanism of the reaction is at hand but in view of the results obtained with the  $\beta$ -bromo acids it seems probable that a simultaneous removal of the bromine atom and the phosphate group is involved. If this elimination took place from the enol form of the keto-acid, it would be a usual case of 1,4 elimination—the reverse of 1,4 addition. Subsequent ketonization of the product would form dibenzalacetone. Considering the fact that this decomposition takes place under conditions which would favor the formation of the enol form, this mechanism seems probable.

The formation of benzaldehyde as another product of this reaction can be attributed to the further decomposition of the unsaturated enol form. The easy decomposition of both these dibromides with the formation of benzaldehyde must be in some such way connected with the presence of the

bromine atom. The unsaturated keto-phosphonic acids themselves are not decomposed under parallel conditions.

### Reaction with Cinnamylidene-acetophenone.

The results obtained with the trichloride and this ketone were very unsatisfactory; a keto-phosphonic acid was obtained but in very small amounts. Phosphenyl chloride, however, gave fair yields. The structure of the product was shown by oxidation with ozone. Benzaldehyde was obtained in large quantities. The reaction thus takes place as shown below, the addition being 1,4 and not 1,6.

### Experimental.

$\alpha$ -Phenyl- $\beta$ -cinnamoyl-ethyl-phosphonic Acid,  $\text{C}_6\text{H}_5\text{CH}(\text{PO}_2\text{H}_2)\text{CHCOCH}=\text{CHC}_6\text{H}_5$ .—This substance was prepared as previously described<sup>2</sup> by the action of phosphorus trichloride on dibenzal-acetone in glacial acetic acid. In attempting to prepare considerable quantities of this acid it was found desirable to crystallize it from hot dil. acetic acid. Considerable amounts of some oily impurities were thus eliminated and the pure acid containing 1.25 mols. of water of crystallization was obtained. The yields were low; about 25% being the average. The rest of the material was apparently converted into some other acidic substance which could not be obtained in crystalline condition.

The acid is not decomposed by alcoholic potassium hydroxide solution either hot or cold. A crystalline potassium salt separates, from which the acid may be obtained by treatment with acid.

Attempts to add another molecule of phosphorus trichloride to this unsaturated ketonic acid failed. Both acetic acid and anhydride were employed as mediums but the monophosphonic acid was recovered unchanged after treatment of the reaction mixture with water. In one experiment the reaction mixture was heated to somewhat below 100°. On treatment with water no unchanged monophosphonic acid could be obtained; the entire product was soluble in water. This points to the formation of a diphosphonic acid, but no substance could be isolated from the water solution.

$\alpha$ -Phenyl- $\beta$ -cinnamoyl-ethyl-phenylphosphonic Acid,  $\text{C}_6\text{H}_5\text{CH}(\text{C}_6\text{H}_5\text{PO}_2\text{H})\text{CHCOCH}=\text{CHC}_6\text{H}_5$ .—Five g. of dibenzal-acetone was suspended in 5 cc. of glacial acetic acid, and 3 cc. (one equivalent) of phosphenyl chloride was added to the mixture. On standing a few moments the ketone dissolved and the fumes of acetyl chloride were noticeable. Within 5 minutes the mixture solidified. The solid was then dissolved by treatment with an excess of 20% sodium hydroxide solution. The aqueous solution was extracted with ether to remove any unchanged ketone and the phosphonic acid precipitated by the addition of hydrochloric acid. The solid was filtered, washed with water and recrystallized from hot glacial acetic acid. The average yield was 53%. The pure substance melts at 235 to 236°; it is almost insoluble in all common solvents.

*Analysis.* Calc. for  $\text{C}_{23}\text{H}_{21}\text{O}_4\text{P}$ : P, 8.3. Found: 8.1.

*Oxidation with ozone.*—One g. of the acid was suspended in 50 cc. of chloroform, and a stream of ozonized oxygen bubbled through the mixture. The ozonized oxygen was

<sup>2</sup> THIS JOURNAL, 39, 2679 (1917).

prepared by electrolysis and was analyzed from time to time by passing a certain amount of it through potassium iodide solution. The gas contained about 4% of ozone, but was not completely free from moisture in spite of passing through a tube of phosphorus pentoxide. The oxidation was considered as complete when about a 20% excess of the theoretical amount of ozone had been passed into the solution. The solvent was evaporated under diminished pressure at a temperature of 40°. The residue was then distilled with steam; 0.2 g. of benzaldehyde was thus obtained and identified by converting into the phenylhydrazone. The residue in the flask consisted of a water solution and a small amount (0.18) g. of gummy material. The water solution on evaporation yielded 0.4 g. of a crystalline solid melting at 212°.

$\alpha$ -Phenyl- $\beta$ -carboxy-ethyl-phenylphosphonic Acid,  $C_6H_5CH(C_6H_5PO_2H)CH_2CO_2H$ .—This acid, obtained as just indicated, could be recrystallized from hot water; it melted at 212°. Titration with 0.2 *N* sodium hydroxide solution showed it to be a dibasic acid with a molecular weight of 289 (calculated 290).

*Analysis.* Calc. for  $C_{13}H_{13}O_4P$ : P, 10.7. Found: 10.8.

$\alpha$ -Phenyl- $\beta$  (dibromo-hydrocinnamoyl)-ethyl-phosphonic Acid,  $C_6H_5CH(PO_2H)CH_2COCHBrCHBrC_6H_5$ .—This substance was prepared by the action of bromine on a chloroform solution of the corresponding unsaturated phosphonic acid. The reaction is accelerated by sunlight; no hydrogen bromide is evolved. The product crystallizes from moist chloroform or aqueous alcohol in fine white needles melting with decomposition at 180 to 182°. They contain 2.5 mols. of water of crystallization. The anhydrous material could be obtained as an oil by working in absolutely dry chloroform or by heating a suspension of the hydrated material in chloroform together with anhydrous calcium chloride. Since the dibromide on heating loses hydrobromic acid as well as water, no direct determination of the water of crystallization was possible. The hydrated material is not soluble in chloroform but can be crystallized from aqueous alcohol.

*Analysis.* Calc. for  $C_{17}H_{17}PO_4Br_2 + 2.5H_2O$ : Br, 30.7. Found: 30.7, 30.6, 30.8.

$\alpha$ -Phenyl- $\beta$ -( $\alpha$ -bromo-cinnamoyl)-ethyl-phosphonic Acid,  $C_6H_5CH(PO_2H)CH_2COCBr=CHC_6H_5$ .—7 g. of the crude crystalline dibromide was suspended in 150 cc. of 95% alcohol and treated with a solution of 3 g. of potassium hydroxide in 100 cc. of 95% alcohol. The mixture was allowed to stand for 2 hours; a considerable amount of potassium bromide separated. The solution was then diluted with an equal volume of water. The small precipitate of dibenzal-acetone (0.1 g.) which formed was filtered off. (This substance was produced by the action of the excess of potassium hydroxide on the monobromide as described later.) The filtrate was acidified and the monobromide precipitated in the form of fine needle crystals. They were recrystallized from aqueous alcohol containing a little acetic acid. 4.5 g. was thus obtained, a yield of 81%. The material thus prepared contains water of crystallization; it melts with the loss of this water at 130 to 132°. It is readily soluble in sodium hydrogen carbonate solution without decomposition. It reduces alkaline potassium permanganate solution instantly but does not combine with bromine. Titration with 0.5 *N* sodium hydroxide solution showed it to be a dibasic acid.

*Analysis.* Calc. for  $C_{17}H_{16}O_4BrP + 1H_2O$ : Br, 19.4. Found: 19.5, 19.4.

A sample of the acid was heated to constant weight at 135° and the resulting melt analyzed for bromine.

*Analysis.* Calc. for  $C_{17}H_{16}O_4BrP$ : Br, 20.2. Found: 20.3.

A sample of the dehydrated material was dissolved in dry ether and saturated with hydrogen bromide. On evaporation an oil was left, which, on treatment with 50% aqueous alcohol yielded the crystalline dibromide previously described. It was identified by a mixed-melting-point determination.

*Oxidation with Ozone.*—One g. of the monobromide was heated to constant weight at 120° and then dissolved in dry chloroform. The solution was treated with ozonized

oxygen in the manner previously described. The solution became red during the process due to the formation of free bromine. This was apparently formed by the hydrolysis of the acid bromide and oxidation of the hydrogen bromide by the ozone. At the end of the oxidation the solution contained a solid which was filtered off; it weighed 0.35 g. (50% yield). The chloroform solution was divided into two parts. One part was shaken with water and the aqueous layer tested for hydrobromic acid which was found to be present in large amount. The other half was evaporated and the residue distilled with steam; no benzaldehyde could be detected, but 0.1 g. of benzoic acid was obtained by crystallization from hot water. The free bromine apparently oxidized the aldehyde to the acid.

$\alpha$ -Phenyl- $\beta$ -glyoxy-ethyl-phosphonic Acid,  $C_6H_5CHPO_3H_2CH_2COCO_2H + 2H_2O$ .—The solid which separated from the ozonized solution melted at  $183^\circ$  with decomposition. Titration with 0.2 *N* sodium hydroxide solution showed that it was a tribasic acid with a molecular weight of 297; the calculated molecular weight is 294.

*Analysis.* Calc. for  $C_{10}H_{11}O_6P \cdot 2H_2O$ : P, 10.5. Found: 10.4.

A sample of the acid was heated to constant weight at  $120$ – $125^\circ$  and then analyzed.

*Analysis.* Calc. for  $C_9H_{11}O_6P$ : P, 13.5. Found: 13.2.

This shows that the ketonic acid on heating loses carbon monoxide and water and yields the acid  $C_6H_5CH(PO_3H_2)CH_2CO_2H$ .

$\alpha$ -Phenyl- $\beta$ -(dibromo-hydrocinnamoyl)-ethyl-phenylphosphonic Acid.—Five g. of the unsaturated monobasic phosphonic acid was suspended in chloroform and treated with bromine. The color of the bromine disappeared rapidly and no hydrobromic acid was evolved; after standing several hours the crystalline dibromide separated. The yield was almost quantitative. On recrystallization from hot glacial acetic acid, however, some material was lost; m. p.  $195^\circ$  with decomposition. The acid dissolves slowly in cold sodium hydrogen carbonate or carbonate solution and may be precipitated unchanged.

*Analysis.* Calc. for  $C_{22}H_{21}O_3Br_2P$ : Br, 29.8. Found: 29.6.

$\alpha$ -Phenyl- $\beta$ -( $\alpha$ -bromo-cinnamoyl)-ethyl-phenylphosphonic Acid.—The dibromide was dissolved in a hot 4% solution of potassium acetate in methyl alcohol. The solution was heated on the steam-bath for a few minutes and then poured into water. A clear solution resulted which on acidification yielded a crystalline precipitate of the monobromide. The yield was 80%; m. p.  $200^\circ$ .

*Analysis.* Calc. for  $C_{22}H_{20}O_3PBr$ : Br, 17.6. Found: 17.6.

*Oxidation with Ozone.*—The monobromide is almost insoluble in chloroform so that a suspension had to be used for the oxidation. Ozonized oxygen was passed through the mixture for many hours in order to complete the oxidation. 0.3 g. of material was oxidized in this way and the chloroform solution then extracted twice with water. The amount of hydrogen bromide in the aqueous layer was determined by the Volhard method.

*Analysis.* Calc. amount of bromide ion: 0.051 g. Found: 0.044 g. or 86%.

In another experiment 0.6 g. was ozonized and the chloroform solution extracted several times with water. The aqueous solution on evaporation to small volume yielded 0.17 g. of the dibasic acid melting at  $212^\circ$ , which was previously obtained by the oxidation of the unsaturated phosphonic acid. The identity of the material was established by mixed-melting-point determinations and titration with standard alkali.

A small amount of benzoic acid was obtained by evaporation of the original chloroform solution.

### The Action of Alkaline Reagents on the Monobromides.

Sodium hydrogen carbonate and sodium carbonate solutions dissolve

both monobromides without decomposition. On acidification the original material is recovered unchanged.

Aqueous 10% potassium hydroxide dissolves both monobromides but the solution soon becomes colored and the odor of benzaldehyde can be detected after the mixture has stood some minutes; small amounts of unsaturated ketone sometimes separate from the solution of the dibasic monobromo acid. No product except benzaldehyde could be identified with the monobasic monobromo acid. On acidification with nitric acid and addition of silver nitrate a heavy precipitate of silver bromide is obtained in every case.

Alcoholic potassium hydroxide rapidly decomposes both monobromides. The solutions become yellow and finally deep red; the odor of benzaldehyde is very evident. On dilution with water dibenzal-acetone is obtained in the case of the dibasic acid; no definite product could be isolated in similar experiments with the monobasic acid. A typical experiment with the dibasic monobromo acid as follows.

0.5 g. of monobromide was added to 20 cc. of 95 % alcohol containing 0.33 g. of dissolved potassium hydroxide. The solution turned yellow, and finally at the end of one hour, deep red. Potassium bromide was precipitated. The odor of benzaldehyde was noticed. After standing overnight the solution was diluted with three times its volume of water. A very fine crystalline precipitate of dibenzal-acetone separated and was filtered off and dried; 0.08 g. was thus obtained which is equivalent to 0.14 g. of the monobromide or 28% of the material used. It was identified by a mixed-melting-point determination.

$\alpha$ -Styryl- $\beta$ -benzoyl-ethyl-phosphonic Acid,  $C_6H_5CH = CHCH(PO_3H_2)CH_2COC_6H_5$ .—No satisfactory results could be obtained by using acetic acid as a medium for adding phosphorus trichloride to cinnamylidene-acetophenone. Acetic anhydride was therefore employed. 15 g. of the ketone was dissolved by gently warming in 15 g. of acetic anhydride. 18 g. of phosphorus trichloride was added to the warm solution and the flask gently warmed several times to the temperature at which acetyl chloride started to boil from the solution. The product after standing for 3 hours at room temperature was poured into 1800 cc. of water. The major portion of the product (about 10 g.) separated as an oil which could not be obtained in crystalline condition. It was completely soluble in sodium carbonate solution and was reprecipitated by acids. It was evidently a mixture of phosphonic acids but no definite substances could be isolated from it. The aqueous solution was decanted from the oil and evaporated to a small volume. About 1 g. of crystalline material was obtained which melted at 159 to 161°. It was soluble in sodium hydrogen carbonate and was oxidized by potassium permanganate solution with the formation of benzaldehyde. It decolorized a chloroform solution of bromine only slowly.

*Analyses.* Calc. for  $C_{17}H_{17}O_4P$ :  $1/4 H_2O$ : C, 63.6; H, 5.5; P, 9.8. Found: C, 63.7; H, 5.7; P, 9.7.

$\alpha$ -Styryl- $\beta$ -benzoyl-ethyl-phenylphosphonic Acid,  $= C_6H_5CH = CHCH(C_6H_5PO_3H)CH_2COC_6H_5$ .—Twenty g. of cinnamylidene-acetophenone was suspended in 20 cc. of glacial acetic acid, and 12 cc. of phosphenyl chloride was added. The ketone slowly dissolved. At the end of 3 hours the mixture was almost solid. The material was treated with water, the solid filtered and recrystallized from hot glacial acetic acid.

20.5 g. of recrystallized product was obtained,—a yield of 64%. The solid melts at 200°. It is insoluble in most solvents.

*Analysis.* Calc. for  $C_{23}H_{21}O_3P$ : P, 8.24. Found: 8.26.

*Oxidation with ozone.*—One g. of the material was suspended in chloroform and treated with ozonized oxygen for the calculated length of time. The solvent was evaporated and the residue distilled with steam. 0.22 g. of benzaldehyde was thus obtained, and 0.1 g. of unoxidized material was found in the residue. The amount of benzaldehyde found is thus about 90% of the amount that could theoretically be obtained from the 0.9 g. of material which was oxidized. In another experiment the residue left after evaporation of the solvent was treated with sodium carbonate solution and filtered from a small amount of oil. On acidification with nitric acid a dark flocculent precipitate was formed. It could not be obtained pure enough for analysis, but it was obviously an acid and contained phosphorus.

### Summary.

1. Phosphorus trichloride and phosphenyl chloride combine with dibenzal-acetone in glacial acetic acid to form unsaturated keto-phosphonic acids.

2. The unsaturated acids thus formed combine with two atoms of bromine and form dibromides. The dibromides on treatment with alkaline reagents easily lose hydrogen bromide and form monobromo acids. The structure of these monobromides was established by oxidation with ozone.

3. The monobromides are easily decomposed by aqueous and alcoholic potassium hydroxide. Benzaldehyde is formed. In the case of one of the monobromides about 25% of dibenzal-acetone is also produced.

4. Unsaturated keto-phosphonic acids are formed by the action of phosphorus trichloride and phosphenyl chloride on cinnamylidene-acetophenone in suitable solvents. The combination takes place in the 1,4 position as shown by oxidation with ozone.

CAMBRIDGE 38, MASSACHUSETTS.

## THE ACTION OF HYDROGEN PHOSPHIDE ON FORMALDEHYDE.

BY ALFRED HOFFMAN.

Received April 18, 1921.

The condensation of hydrogen phosphide with aldehydes was studied by Messinger and Engels.<sup>1</sup> By passing a mixture of hydrogen phosphide and dry hydrogen chloride into ethereal solutions of the aldehydes they obtained compounds of the composition  $(R.CHO)_4PH_4Cl$ . Treated with potassium hydroxide these gave products assumed by the authors to be mixtures of the free phosphine and its hydrate. Similar compounds have been prepared by Girard,<sup>2</sup> by the action of phosphonium iodide on aldehydes. Formaldehyde was not investigated by either of these authors.

<sup>1</sup> Messinger and Engels, *Ber.*, 21, 325 (1888).

<sup>2</sup> Girard, *Ann. chim.*, [6] 2, 2 (1884).

In the experiments here described, it was found that hydrogen phosphide is readily absorbed when passed into a warm, aqueous solution of formaldehyde acidified with hydrochloric acid. On evaporation the solution gives a crystalline salt, which has the properties of a tetrahydroxymethylene-phosphonium chloride,  $(\text{HOCH}_2)_4\text{PCl}$ .

This substance is quite stable; its aqueous solution may be boiled without decomposition and it is unaffected by dil. acids. It reduces silver nitrate solution in the cold and is easily oxidized by conc. nitric acid. It is extremely sensitive toward alkalis and even neutral carbonates. With caustic soda solution, even in the cold, a vigorous evolution of hydrogen takes place. When the latter is completed by heating, it is found that exactly four atoms of hydrogen are split off. When this experiment was performed in an open tube, a slight odor of methyl alcohol was detected. If the solution is then acidified with hydrochloric acid and distilled to dryness, half a molecule of formic acid comes over. The residue of the molecule containing the phosphorus is more easily isolated when the decomposition is carried out with barium hydroxide. After removing the barium and evaporating, a thick colorless sirup remains which does not crystallize. According to the yield and to the percentage of phosphorus, the compound seems to have the empirical formula  $\text{C}_6\text{H}_9\text{O}_5\text{P}$ , perhaps constituted  $(\text{HOCH}_2)_3\text{PO}_2$ . As the course of the reaction and the constitution of the compound need further clearing up, the formula is given with due reserve. The reaction may be as follows,

The formaldehyde then reacts with the sodium hydroxide to give half methyl alcohol and half formic acid. The syrupy compound is rather difficult to oxidize with nitric acid. It has feeble acid properties, forming salts, with barium carbonate, for instance, which hydrolyze on evaporating the solution. By means of the Schotten-Baumann reaction the substance gives a well crystallizing tribenzoyl derivative.

With neutral carbonates, such as calcium carbonate the action is similar, but less vigorous, and there are indications of the formation of intermediate products. On adding the carbonate to the aqueous solution of the crystalline phosphonium chloride, an evolution of carbon dioxide is observed, due to the union of the chlorine with the calcium; then on heating, a slow evolution of hydrogen takes place and one molecule of formaldehyde distills. Also a disagreeable odor is noticed, perhaps the trihydroxymethylene-phosphine. It was not found possible to isolate these intermediate compounds either as such or as benzoyl derivatives. The final product in this case also was the syrupy compound.

Of special interest is the action of ammonia on the crystalline phosphonium chloride. If dil. aqueous solutions are employed, the ammonia acts like an alkali, hydrogen is evolved and the solution remains clear.

If, however, concentrated solutions are used, a curdy white precipitate is formed in small amount. By working under anhydrous conditions in methyl alcohol, larger yields are obtained; but the best yields, up to almost 50% of the weight of phosphonium chloride taken, are obtained in aqueous solution with ammonium chloride and a neutral carbonate or bicarbonate. As the substance contains almost twice as much phosphorus as the phosphonium chloride, the reaction is nearly quantitative. The ammonia derivative is a curdy, somewhat stringy, white precipitate. It is very voluminous and retains the bubbles of carbon dioxide from the carbonates, so that in fairly concentrated solutions a spongy, dough-like mass is obtained. The compound is insoluble in water, dilute acids and alkalis and all the ordinary organic solvents, but on boiling with water for several days it goes into solution, giving the ammonia salt of a complex organic phosphoric acid. It is easily soluble in cold dil. formaldehyde solution, giving a clear solution, which on evaporation leaves a spongy horn-like mass, having a pronounced fishy odor, like trimethylamine. The ammonia derivative is quite stable to heat. At a temperature far above 200°, it suddenly swells, gives off an odor of decayed fish and burns with a flame. With concentrated nitric acid it reacts violently, often catching fire. Its composition seems to vary somewhat. The percentage composition is phosphorus, 27 to 30%; nitrogen, 14.5 to 16.2%. The filtrate from the preparation of the ammonia derivative contains hexamethylene-tetramine, which could be isolated by extracting the dried residue from the solution with chloroform. Its amount corresponds roughly to one molecule of formaldehyde for each molecule of the phosphonium chloride taken, but seems to vary somewhat. The ammonia derivative is not formed from the syrupy compound. Considerable further study will be necessary to determine the constitution of the substance, as, to judge from its physical properties, it must be of high molecular weight. It may be mentioned that aniline gives a similar precipitate with the phosphonium chloride but urea does not. The work is being continued.

### Experimental.

**Hydrogen Phosphide.**—To prepare this gas, small quantities of a mixture of two parts aluminum powder and one part red phosphorus were prepared on a piece of paper on an asbestos pad. On igniting the paper, the mixture became white-hot and there resulted a spongy mass of aluminum phosphide.<sup>3</sup> This substance reacts with cold water to give a steady stream of hydrogen phosphide. The gas so formed is not spontaneously inflammable at room temperature, but does ignite at the temperature of the following experiment (80°), causing small explosions in the apparatus.

**Tetrahydroxy-methylene-phosphonium chloride.**—A mixture of 90 cc. of 40 % formaldehyde solution and 40 cc. of hydrochloric acid, (sp. gr. 1.2) was introduced into a 100-cc. 3-bulb Ladenburg flask (it should fill about half of the neck of the flask), the latter provided

<sup>3</sup> Fonze-Diacon, *Compt. rend.*, 130, 1314 (1900); Bodroux, *Bull. soc. chim.*, [3] 27, 568 (1902).

with a stopper through which passed a gas-delivery tube reaching to the bottom. The flask was then inclined to an almost horizontal position, hydrogen phosphide was passed in to displace the air and the solution then heated to about  $80^{\circ}$ . At lower temperatures the reaction is correspondingly slower and at higher temperatures the vapor pressure of the solution interferes with the absorption. The bulbs of the flask serve to hold back the gas and make the reaction more complete. Hydrogen and some hydrogen phosphide escape from the side-neck and should be led off to a flue. Using 10 portions of each 4 g. of aluminum and 2 g. of phosphorus, the reaction was complete in two days. The liquid was evaporated on the steam-bath, with stirring toward the end until a white granular mass was obtained; yield, 50 g. (calculated yield, 57 g.). This is pure enough for preparative purposes. For analysis it was crystallized from glacial acetic acid, 1 g. of substance to 50 g. of acid. It crystallizes in flat needles of low melting point containing acetic acid of crystallization, which can be removed in a current of dry air at  $100^{\circ}$ . The pure substance melts at  $151^{\circ}$ , is very deliquescent, easily soluble in methyl alcohol, slightly in hot chloroform and insoluble in ether. It reacts with acetyl chloride and acetic anhydride to give oily products.

*Analysis.* Subs., 0.198: AgCl, 0.150. Subs., 0.217:  $Mg_2P_2O_7$ , 0.127. Calc. for  $C_4H_{12}O_4P_2Cl$ : Cl, 18.6; P, 16.2. Found: Cl, 18.68; P, 16.1.

**Action of Sodium Hydroxide.**—*Analysis.* Subs., 0.175: 44.7 cc. moist hydrogen at  $12^{\circ}$ , 750 mm. = 41.6 cc. dry hydrogen at  $0^{\circ}$ , 760 mm. Calc. for two molecules of hydrogen: 41.1 cc.

After acidifying with hydrochloric acid and distilling to dryness, the distillate was neutralized and treated with mercuric chloride solution.<sup>4</sup>

*Analysis.* Subs., 0.976:  $Hg_2Cl_2$ , 1.315 = 0.128 g. formic acid. Calc. for 0.5 molecule formic acid: 0.118 g.

**Action of Barium Hydroxide.**—*Analysis.* Subs., 0.691, treated with barium hydroxide solution and the barium removed quantitatively, gave 0.556 g. of syrup dried to constant weight. Calc. for  $C_3H_5O_3P$ : 0.567 g. 0.526 g. of sirup gave 0.364 g.  $Mg_2P_2O_7$ . Calc. for  $C_3H_5O_3P$ : P, 19.8. Found: 19.3.

**Action of Calcium Carbonate.**—*Analysis.* Subs. 1.008 in aqueous solution distilled with calcium carbonate and the distillate treated with a solution of mercuric chloride, sodium hydroxide and sodium sulfite<sup>5</sup> gave 1.116 g. Hg. Calc. for one molecule formaldehyde: 0.159. Found: 0.167.

**Preparation of the Tribenzoyl Derivative of the Syrupy Compound.**—The crystalline phosphonium chloride was boiled with a large excess of sodium hydroxide solution, (1–10), until no more hydrogen was given off, and the solution was cooled and shaken with a slight excess of benzoyl chloride until the oil solidified. Fine needles were obtained on crystallization from methyl alcohol, m. p.  $111^{\circ}$ , easily soluble in hot methyl alcohol but insoluble in water.

*Analysis.* Subs., 0.402 g:  $Mg_2P_2O_7$ , 0.100. Calc. for  $(C_6H_5COOCH_2)_3PO_2$ : P, 6.62. Found: 6.94.

### Summary.

The action of hydrogen phosphide on a warm, aqueous solution of formaldehyde, acidified with hydrochloric acid, was studied and the reaction product tetrahydroxy-methylene-phosphonium chloride isolated and its properties studied. By the action of alkalis or carbonates on the

<sup>4</sup> "Beilstein," 4th ed. Vol. II, p. 13.

<sup>5</sup> "Beilstein," 4th ed. Vol. I, p. 570.

latter, a compound,  $C_3H_5O_3P$ , was formed and its tribenzoyl derivative prepared. The action of ammonium chloride and calcium carbonate on tetrahydroxy-methylene-phosphonium chloride was studied and an insoluble curdy precipitate containing about 30% of phosphorus and 15% of nitrogen obtained.

### SOME DERIVATIVES OF SALIGENIN.<sup>1</sup>

By MERRILL C. HART AND ARTHUR D. HIRSCHFELDER.

Received April 20, 1921.

Since Hirschfelder, Lundholm and Norrgaard<sup>2</sup> have shown that saligenin (*o*-hydroxy-benzyl alcohol) possesses valuable properties as a local anesthetic it was thought that an investigation of some of the derivatives of saligenin might also prove valuable. In this study it is desired to vary the saligenin molecule in several different ways and to study pharmacologically the different properties of the derivatives.

The saligenin molecule was first altered by varying the phenolic hydroxyl and simple ethers (Formula I) were synthesized. In this case ethers where R was both aliphatic and aromatic were prepared. The ethyl

(I).

(II).

(III).

propyl, *n*-butyl, *iso*-amyl, and the benzyl ethers of saligenin were made.

Other variations of the molecule were then prepared by making the esters of saligenin (Formula II) upon the phenolic hydroxyl. Representatives of this class of compounds were made by preparing the mono-acetate and the monobenzoate of saligenin. The mono-acetate was particularly desired because of its relation to acetyl salicylic acid (aspirin).

Also a derivative of saligenin, the dibenzoate, was prepared as a representative of the case where both the groups in the saligenin molecule were masked (Formula III).

The saligenin molecule was next modified by varying the nucleus. As the simplest and easiest way of doing this seemed through the introduction

<sup>1</sup> This work was done with the aid of funds granted by the United States Interdepartmental Board, for the investigation of the antiseptic and chemotherapeutic action of phenolic alcohols and their derivatives upon the gonococcus and the spirochaete.

<sup>2</sup> Hirschfelder, Lundholm and Norrgaard, *Science, N. S.*, 51, 21 (1920); *J. Pharmacol.* 15, 263 (1920).

of halogen into the nucleus, the monobromo and mono-iodo saligenin were prepared. It was necessary to produce these in fairly large quantities because they were used not only for pharmacological and clinical study, but they were found also to react slowly with mercuric acetate in dilute alcohol solution with the formation of mercury derivatives. It was desired to study these mercury derivatives both chemically and pharmacologically in comparison with the mercury derivative of saligenin.<sup>3</sup>

Of the ethers of saligenin (Formula I) we found that Cannizaro and Koerner<sup>4</sup> had prepared the methyl ether by treating molecular quantities of saligenin and potash in methyl alcohol with methyl iodide. Later this work was repeated by Pschorr, Wolfes and Buckow.<sup>5</sup> The methyl ether is an oil boiling at 240° with a pleasant ethereal odor.

Bötsch<sup>6</sup> prepared the ethyl ether of saligenin by heating an aqueous solution of saligenin with the theoretical amount of potassium hydroxide and ethyl iodide in a sealed vessel for 3 hours at 100°.

In this research the saligenin ethers were prepared by refluxing potassium saligenate with alkyl or aryl halides. The monosaligenin esters were made by the action of acid chlorides or acid anhydrides on potassium saligenate in ether or alcohol solutions. The dibenzoyl derivative may be prepared by the benzylation of saligenin in pyridine solution in the presence of calcium carbonate.

The methods of preparing monobromo-saligenin were studied and that of Auwers and Büttner<sup>7</sup> was found to be the best. The mono-iodo-saligenin has been made by Seidel<sup>8</sup> by treating saligenin in alcohol with iodine in the presence of mercuric oxide. We found that a better method for the preparation of this compound was to treat saligenin in water solution with a potassium iodide solution of iodine.

Most of the above syntheses required the use of potassium saligenate. This had been made by R. Rivals<sup>9</sup> but his method was not suitable for the preparation of potassium saligenate in quantity. We found that by treating saligenin in acetone solution with alcoholic potash, we could obtain practically theoretical yields of potassium saligenate.

### Experimental Part.

**Preparation of Potassium Saligenate.**—The saligenin used in these experiments was prepared according to the method given by us in a previous paper.

10 g. of pure saligenin was dissolved in 150 mls of acetone. To this was added 35 mls of a 25% solution of potassium hydroxide. A voluminous white precipitate

<sup>9</sup> R. Rivals, *Ann. chim., phys.*, 12, 556 (1897).

dried ether was then evaporated by a current of air. A white crystalline solid was obtained. The crystals were fine needles. This material was dried on a clay plate after having been extracted with a little petroleum ether. 18 g. (67.2% yield) was obtained. The melting point was 51°.

This substance was crystallized from 70% alcohol by taking it up in the alcohol at 50° and then cooling in a vacuum desiccator. When crystallized in this manner the dibenzoate came down as white feathery clusters of needle-like crystals. The melting point, 51°, was not raised by further crystallization.

This compound was very soluble in the usual organic solvents, very sparingly soluble in petroleum ether, and insoluble in water and glycerine. It gave no coloration with ferric chloride. On hydrolysis with alcoholic potash it gave benzoic acid, melting at 122°.

**Analysis of the Dibenzoate of Saligenin.**—The material from the crystallization from the dilute alcohol was dried to constant weight in a vacuum. A small sample was dissolved in 20 mls of 3% alcoholic potash and heated under a reflux condenser for 2 hours. Ten mls of water was added during the process of heating. At the end of this time the solution was diluted with 100 mls of water and extracted with ether. The alkaline solution was then made acid and extracted with ether thrice. The ether extracts were evaporated by a current of air and the residue dissolved in neutral alcohol and titrated with 0.1 *N* sodium hydroxide solution.

**Analysis.** Subs., 0.5153; 0.1 *N* NaOH, 30.84 mls. Calc. for  $C_6H_4(OCOC_6H_5)_2$  ( $CH_2OCOC_6H_5$ ):  $C_6H_5COOH$ , 73.49. Found: 73.07.

**Monobromo-saligenin** (2-hydroxy-5-bromo-benzyl alcohol).—This was prepared by the method of Auwers and Büttner.<sup>7</sup> Several other methods were tried for the preparation of this compound but the above gave the best results.

**Potassium Salt of Monobromo-saligenin.**—One g. of monobromo-saligenin was dissolved in 15 mls of acetone, and 2 mls of 25% alcoholic potash was added. A heavy white precipitate of the potassium salt of the monobromo-saligenin was obtained. It crystallized in fine white microscopic plates. It is extremely soluble in water, is soluble in alcohol, and is sparingly soluble in ether, petroleum ether, and acetone. On acidifying an aqueous solution of it crystalline microscopic plates of the monobromo-saligenin melting at 110° are obtained.

This potassium salt of monobromo-saligenin is also formed when monobromo-saligenin acetate (2-hydroxy-5-bromo-benzyl acetate) is treated in acetone solution with alcoholic potash.

**Mono-iodo-saligenin** (2-hydroxy-5-iodo-benzyl alcohol).—As Seidel<sup>8</sup> from 8.5 g. of saligenin obtained only 1 g. of the mono-iodo compound, it was quite necessary to find a method that would give greater yields. We found that a better method for the preparation of this compound was to treat saligenin in aqueous solution with a solution of iodine in 40% potassium iodide solution. 10 g. of saligenin was dissolved in 500 mls of water and to this was added a solution of 20 g. of iodine in 100 mls of 40% potassium iodide solution. This was allowed to stand for a week as much as possible in the sunlight. At the end of this time the solution was treated with solid sodium hydrogen carbonate until it turned light yellow. A pinkish white precipitate slowly formed and was filtered off. This precipitate was crystallized from hot water. Several extractions were necessary, the later yielding the purer product. The various crops obtained by this method melted from 128 to 130° in the case of the first, to 134 to 136° in the case of the last. Another crystallization from water was sufficient to give pure mono-iodo-saligenin melting at 138°. From 40 g. of saligenin, 12 g. of the pure mono-iodo-saligenin was obtained. This was in the form of white silky needles, melting at 138°.

**Potassium Salt of Iodo-saligenin.**—This was formed in a similar manner to that of the potassium salt of monobromo-saligenin. It consisted of fine white crystalline plates,

very soluble in water, soluble in alcohol, and sparingly soluble in acetone and petroleum ether. On treating an aqueous solution of it with acetic acid, crystals of the mono-iodo-saligenin, melting at 138° are obtained.

### Summary.

1. A method has been developed of treating saligenin in acetone solution with alcoholic potash by which practically theoretical yields of the potassium saligenate were obtained. This method was also used successfully in the preparation of the potassium salts of monobromo- and mono-iodo-saligenin.

By the reaction of potassium saligenate on ethyl iodide, the ethyl ether of saligenin identical with ethyl ether of saligenin prepared by Bötsch was prepared. In an analogous manner the propyl, *n*-butyl, *iso*-amyl, and benzyl ethers of saligenin were made.

3. The mono-acetate and the monobenzoate of saligenin were prepared from potassium saligenate and acetic anhydride and benzoyl chloride, respectively. The dibenzoate of saligenin was made by the benzoylation of saligenin in pyridine in the presence of calcium carbonate and with a slight excess of the benzoyl chloride.

4. The method of Auwers and Büttner for preparation of monobromo-saligenin by the bromination of saligenin in aqueous solution was found to give the best results.

5. For the preparation of mono-iodo-saligenin the best method found was the treatment of saligenin dissolved in water with an aqueous potassium iodide solution of iodine.

## SOME ERRORS IN THE STUDY OF INVERTASE ACTION.

BY WARREN C. VOSBURGH.<sup>1</sup>

Received April 28, 1921.

It was pointed out by Nelson and Vosburgh<sup>2</sup> that a source of error about which little was known existed in the measurement of the velocity of hydrolysis of sucrose by invertase. The trouble was thought to consist in a change in activity which took place when invertase solutions were diluted, and the magnitude of the resulting error was found to vary with different invertase preparations. In some recent experiments an invertase preparation particularly subject to this error was used and as considerable accuracy in the experimental work was necessary for the purpose in view the results were of little value. An investigation was therefore undertaken of

<sup>1</sup> National Research Fellow.

<sup>2</sup> Nelson and Vosburgh, *THIS JOURNAL*, 39, 807 (1917).

the errors in the study of invertase action and a determination of how they may be reduced in magnitude.

### Experimental.

The procedure used in the above mentioned investigation was the following. An invertase and a sugar solution were prepared separately in concentrations twice those at which the invertase and sugar were desired in the finished solution. Equal volumes of the two were mixed to start the reaction and samples taken from time to time. Enough hydrochloric acid to bring the hydrogen-ion concentration to the desired value was usually included in the invertase solution. The most probable points in the procedure at which loss of activity might occur are where the solution containing the invertase is diluted. Therefore an invertase solution was diluted in different ways and the activities of the resulting solutions were compared.

**Dilution of Invertase with very Dilute Acid Solutions.**—The concentration of acid was so chosen that if the dilute invertase were mixed with an equal volume of a solution containing 20 g. of sucrose per 100 cc., but no buffer, the hydrogen-ion concentration of the resulting solution would be about  $4 \times 10^{-5} M$ . The hydrogen-ion concentration of the dilute invertase was therefore a little less than  $4 \times 10^{-5} M$ . Five cc. of the stock invertase was added to about 80 cc. of a solution containing the amount of acid or other substance shown in Col. 2 of Table 1, and the solution made up to 100 cc. A sugar solution was prepared containing 5 g. of sucrose, 21.9 cc. of water, or water containing some buffer. Both solutions were brought to the temperature of the thermostat,  $25^\circ \pm 0.01^\circ$ , 25 cc. of the dilute invertase was added to the sugar solution and the reaction allowed to proceed for exactly 2 hours. A 25-cc. sample was then run into 5 cc. of 0.01 molar sodium carbonate solution, and the optical rotation determined. The solutions at the start of the reaction all contained 5 g. of sucrose, 1.25 cc. of the stock invertase and 5 cc. of citrate and hydrochloric acid buffer solution<sup>3</sup> in 50 cc.<sup>4</sup> The hydrogen-ion concentration was determined colorimetrically<sup>5</sup> in each experiment, and varied only to a negligible extent in the various experiments. The results are shown in Table I.

It is shown in Table I that dilution of definite amounts of invertase with small amounts of various substances present gives solutions which vary in activity according to the substance present during dilution. Thus the presence of hydrochloric or sulfuric acid causes a noticeable loss in

<sup>3</sup> Buffer No. 1. See below.

<sup>4</sup> The small amount of acid in the dilute invertase and the alkali which was sometimes included in the sugar solution to neutralize it were considered negligible.

<sup>5</sup> The procedure was that used by Nelson and Vosburgh, *loc. cit.* The values are based on the assumption that the hydrogen-ion concentration of 0.1 *M* hydrochloric acid is 0.0920 *M*.

TABLE I.

Dilution of Invertase in the Presence of Various Substances.

The invertase solution was prepared by diluting 5 cc. of the stock solution with about 80 cc. of a solution containing substances noted in Col. 2, and making up to 100 cc. with water. 25 cc. was added to the sugar solution to start the reaction.

The sugar solution contained 5 g. sucrose, *a* cc. of solutions noted in Col. 3 and (21.9 — *a*) cc. of water.

<sup>b</sup> Contains also 0.3 cc. of 0.01 N NaOH.

activity if the experiments in which the dilution is made with water only are taken as a standard. It is to be noted also that duplicate determinations in the case of dilution in the presence of hydrochloric or sulfuric acid agree poorly among themselves. Weak acids also cause losses in activity but duplicate determinations agree in this case. Different acids cause losses of different magnitudes.

The presence of a buffer causes a small loss in activity when all is included in the invertase solution and apparently a gain when half is in the invertase and half in the sugar. However, in both cases the results of duplicate

determinations do not agree well. It is strange that a citrate buffer in about 0.01 molar concentration should cause less loss in activity than citric acid at a much smaller concentration. Sodium chloride in 0.01 molar concentration acts much like citric acid.

**Reproducibility of Dilution with Water.**—The main conclusion to be drawn from Table I is that if an invertase solution is to be diluted with minimum loss in activity and in such a way that duplicate determinations of its activity will agree within less than 10 parts per thousand, the dilution must be made with pure water. The experiments listed in Table II show the degree of reproducibility of dilution with water. The procedure was like that of those experiments of Table I in which pure water was used for dilution of the invertase.

TABLE II.  
Reproducibility of Dilution with Water.

Five-cc. portions of invertase No. 3 were diluted to 100 cc. with water and 25 cc. added to a sugar solution containing 5 g. of sucrose, 16.9 cc. of water and 5 cc. of buffer No. 1.

Expt.	22.	23.	24.	25.	9.	35.	38.
Conc. $H^+ \times 10^6$ . . . . .	4.3	3.9	...	4.0	4.0	4.0	4.0
Rotation after 2 Hrs. . . . .	0.25	0.25	0.23	0.22	0.23	0.28	0.23
Change in 2 Hrs. . . . .	12.81	12.81	12.83	12.84	12.83	12.78	12.83

It is evident from Table II that in the dilution of invertase solutions with water duplication of results within 5 parts per thousand is possible. However dilution of 5 cc. of the stock solution to 100 cc. only is considered. Nelson and Hitchcock<sup>6</sup> have found that poor duplication resulted after a dilution considerably greater than this.

**Loss in Activity on Adding Invertase to a Sugar Solution.**—The total loss in activity before the beginning of the reaction must be the sum of the loss due to the preliminary dilution of the invertase and that taking place on mixing with the sugar solution. In drawing the conclusions above it has been assumed that the second loss is either constant or small compared with the first. It seems reasonable to conclude from Table II that if the presence of a citrate buffer has any effect at this point the effect is reproducible within at most 5 parts per thousand and therefore that the above assumption is justified. The effect of some other sources of hydrogen ion when used instead of the buffer is shown in Table III. The experiments were carried out according to the same procedure as those of Table I, the invertase being diluted with water only and the substances noted in Col. 2 being present in the respective sugar solutions.

In the experiments of Table III the differences in the change in rotation can be ascribed to changes in the activity of the invertase at the time of mixing with the sugar solution or to different rates of reaction. The

76	0.3	0.005 <i>M</i> Tartaric Acid	3.5	0.70	12.37

latter explanation seems less probable. Retardation similar to that found by Fales and Nelson<sup>7</sup> to be caused by sodium chloride cannot have taken place since the concentrations of electrolyte were small, the hydrogen-ion concentration was the optimum, and the largest concentration of electrolyte was present in the experiment in which the fastest reaction took place. Since dilution of the stock invertase with very weak electrolyte solutions is attended by a loss in activity it is reasonable to expect that dilution of an invertase solution with a sugar solution containing the same electrolyte would also be attended by a loss in activity. Therefore it is assumed that the differences in reaction velocity in the various experiments were chiefly due to changes in activity of the invertase on mixing with the sugar solution.

The results of dilution with a sugar solution containing various sources of hydrogen ion are similar to the results of dilution of the stock invertase with water containing the same substances. A greater loss in activity takes place when free acids are the source of hydrogen ion than when a buffer is used. However the loss in activity caused by the strong acids is here less than that caused by the weak ones. The magnitude of the losses is in most cases much smaller than those in the experiments of Table I. This might be explained as due to the smaller amount of dilution, 25 cc. to 50 cc. as compared with 5 to 100, or it might be explained as the result of "protective action"<sup>8</sup> of the sugar.

<sup>7</sup> Fales and Nelson, *THIS JOURNAL*, 37, 2769 (1915).

<sup>8</sup> O'Sullivan and Thompson, *J. Chem. Soc.*, 57, 900 (1890), have shown that sucrose protects invertase from destruction by hot water; and Hudson, *THIS JOURNAL*, 32, 988, 1354 (1910) has shown that fructose also protects it from destruction by hot water as well as by acids and alkalies, and that sucrose protects it from destruction by alcohol.

That sucrose has such a protective action in this case is shown in the experiments of Table IV. In these, 5 cc. of the stock invertase was added directly to 195 cc. of a solution containing 20 g. of sucrose, and either 20 cc. of buffer or the quantity of acid necessary to make the hydrogen-ion concentration of the completed solution about  $4 \times 10^{-5} M$ . The concentrations of invertase, sucrose, and hydrogen ions are consequently the same as in the experiments of Table III, only the total volume and manner of mixing differing.

TABLE IV.

Rate of Hydrolysis when No Preliminary Dilution is Made.

The sugar solution contained 20 g. of sucrose, (182.6 — *a*) cc. of water and *a* cc. of acid or buffer as noted in Col. 3. 5 cc. of Invertase 3 A was added.

Expt.	Sugar solution contains, Cc.	Solution.	Conc. $H^+$ $\times 10^5$ .	Rotation after 2 hrs.	Change in 2 hrs.
60	20	Buffer No. 1	4.0	0.17	12.89
61	20	Buffer No. 1	4.1	0.17	12.89
78	20	Acetate Buffer	4.3	0.22	12.84
83	20	Acetate Buffer	4.1	0.29	12.77
87	1.4	0.005 <i>M</i> $H_2SO_4$	4.7	0.45	12.61
80	2.3	0.005 <i>M</i> Citric Acid	4.4	0.42	12.64
86	2.1	0.005 <i>M</i> Citric Acid	5.1	0.39	12.67
81	4.8	0.01 <i>M</i> Acetic Acid	5.5	0.39	12.67
84	4.3	0.01 <i>M</i> Acetic Acid	5.1	0.45	12.61

The results given in Table IV are similar to those in Table III. Dilution with a sugar solution containing a very weak electrolyte evidently has less destructive action than dilution with a very weak electrolyte in absence of sugar. Expts. 60 and 61 as compared with Expts. 45 and 70 in Table III show that in the latter there is a loss in activity on dilution of the invertase with water.

It seems reasonable that the best procedure to adopt in the study of invertase action is that which will give the fastest reaction, other conditions being the same. The experiments of Tables III and IV point out therefore that the invertase should be used without preliminary dilution if possible, and that buffers are preferable to acids as the source of hydrogen ions.

**Experiments with Other Invertase Preparations.**—Experiments similar to some of the above experiments were carried out with two other invertase preparations, Nos. 2 and 8, and the results are given in Tables V, VI, and VII. The procedure was essentially the same as in the experiments of Tables I, III and IV respectively.

It is shown in Table V that dilution in presence of hydrochloric acid has some destructive action on Invertases 8 and 2 but the amount is noticeably less than that in the case of Invertase 3. In case of Invertase 2 it is probable that the amount of acid used was not equal with respect to the dilution effect to that used with Invertases 3 and 8, since more

135	1.1	0.01 M HCl <sup>a</sup>	3	4.3	4.87	8.25

<sup>a</sup> Sugar solution contained 0.3 cc. of 0.01 M NaOH, 16.6 cc. of water and 5 cc. of buffer to 5 g. of sucrose.

<sup>b</sup> Citrate and hydrochloric acid buffers.

acid was required to bring a solution containing Invertase 2 in the concentration used to a hydrogen-ion concentration of  $4 \times 10^{-5} M$  than in the case of Invertases 3 and 8. The magnitude of the dilution effect on Invertase 8 seems to be somewhat dependent on the hydrogen-ion concentration, the loss in activity being larger when the acid concentration is larger. Therefore although the observed loss in activity by Invertase 2 is small, it probably would be somewhat larger if an amount of acid equivalent to that in the experiments with Invertase 8 were present.

It can be concluded from Table V that dilution of any invertase in presence of hydrochloric acid is likely to result in loss in activity, but that the magnitude of the losses under the same conditions differs in different invertase preparations. Invertase solutions may be classified according to stability, the more stable ones being those like Nos. 2 and 8 which lose the least on dilution and the less stable being those like No. 3. Dilution with water is reproducible within 2 parts per thousand in the case of Invertases 8 and 2.<sup>9</sup>

<sup>9</sup> The rather large difference between Expts. 125 and 132 with Invertase 2 may have been due to decrease in activity of the stock solution during the 11 days which elapsed between the two experiments, the solution having been removed from the ice-box during part of 1 day. In view of this the experiments with Invertase 2 numbered above 128 should be compared with No. 128 rather than with No. 125, and those numbered below 125 should be compared with the latter.

TABLE VI.

Effect on Invertases 2 and 8 of Acids when Present in the Sugar Solution Previous to Adding the Invertase.

Procedure as in the experiments of Table III except that a 10-cc. portion of Invertase 2 was used.

## A. Invertase No. 8.

Expt.	Sugar solution contains,		Conc. H <sup>+</sup> × 10 <sup>3</sup> .	Rotation after 2 hrs.	Change in 2 hrs.
	Cc.	Solution.			
90	5	Buffer No. 1	3.8	-1.09	14.14
96	5	Buffer No. 2	4.4	-1.07	14.12
93	0.25	0.01 M HCl	3.4	-1.03	14.08
97	0.27	0.01 M HCl	3.6	-1.07	14.12
123	0.30	0.01 M HCl	5.0	-1.00	14.05
99	0.38	0.005 M Citric Acid	3.7	-1.05	14.10
100	0.38	0.005 M Citric Acid	3.7	-1.05	14.10

## B. Invertase No. 2.

125 <sup>a</sup>	5	Buffer No. 3	4.3	4.79	8.33
132	5	Buffer No. 3	3.7	4.84	8.28
138	5	Buffer No. 3	4.5	4.85	8.27
126	0.35	0.01 M HCl	3.7	4.91	8.21
139	0.37	0.01 M HCl	4.2	4.94	8.18
140	0.52	0.005 M Citric Acid	4.3	4.86	8.26
141	0.52	0.005 M Citric Acid	4.4	4.87	8.25

<sup>a</sup> See note above.

Table VI shows that the conclusions drawn from Table III can be extended to apply to other invertase preparations, except as to the magnitude of the losses in activity under the various conditions. The change in rotation in the experiments with citric acid as the source of hydrogen ions is only 2 to 3 parts per thousand less than in the experiments in which buffer is used. With the more stable invertase preparations therefore citric acid can be used as the source of hydrogen ions instead of a buffer. Hydrochloric acid is less reliable as to reproducibility and should not be used when results of high precision are desired.

TABLE VII.

Rate of Hydrolysis when No Preliminary Dilution is Made.

The procedure was like that of the experiments of Table IV. Five cc. of invertase was used in each experiment.

Expt.	Invertase No.	Buffer No.	Cc.	Sucrose. G.	Water. Cc.	Conc. H <sup>+</sup> × 10 <sup>3</sup> .	Rotation after 2 hrs.	Change in 2 hrs.
105	8	2	20	20	162.6	4.3	-1.11	14.16
106	8	2	20	20	162.6	4.6	-1.11	14.16
136	2	3	10	10	78.8	4.3	4.82	8.30
137	2	3	10	10	78.8	4.3	4.83	8.29

Comparison of the experiments in Table VII in which no preliminary dilution was made with those of Table V in which preliminary dilution was

made shows that in the case of Invertases 8 and 2 only small losses in activity took place on dilution with water, the change in rotation being about 3 parts per thousand<sup>10</sup> larger than in the case in which no preliminary dilution was made. The difference between stable and unstable invertase preparations is noticeable in the amount of loss in activity caused by dilution with distilled water.

**Loss in Activity by Dilute Invertase on Standing.**—In the above experiments the dilute invertase solutions were used within 2 hours after preparation. It was found that such solutions when kept at 25° lost activity as time went on. For example in an experiment with Invertase 3A the change in rotation using the freshly prepared dilute invertase was 12.78°, while that after the solution had been kept for one day was 12.69°. The activity decreased regularly and after 11 days the change in rotation was 12.38°. When a similar solution was kept in the ice-box the loss in activity was much slower, but still appreciable. In this case the change in rotation when the invertase was freshly diluted was 12.48° and after 20 days was 12.35°.

A similar loss in activity takes place in dilute solutions of other invertase preparations. In the case of the dilute Invertase 8 used in Expt. 96<sup>11</sup> determinations after 1 and 4 days' standing at 25° gave respectively 13.98° and 13.82° change in rotation as compared with 14.12° in Expt. 96. The dilute Invertase 8 used in Expt. 122<sup>11</sup> was kept in the ice-box for 12 days after which the change in rotation was 13.99° as compared with 14.15° in Expt. 122. In the case of Invertase 2 the dilute solution of Expt. 138, giving in that experiment a change in rotation of 8.27° gave after 5 days in the ice-box 8.03°.

Hudson and Paine<sup>12</sup> claim that destruction of invertase by acids or alkalis is only appreciable when the acid or alkali concentration is 0.01 molar or greater. The hydrogen-ion concentration of a dilute solution of Invertase 3A was found to be 5.77 when freshly diluted, and after 5 days 5.84. This would indicate that the loss in activity is due to some other cause than the destructive action of acids or alkalis. On the other hand when a small amount of acid was present in the dilute invertase it was found that the loss in activity in two days was much greater than the loss during the same time by a solution made up without acid.

**Loss in Activity by Stock Solutions.**—Fales and Nelson<sup>7</sup> reported that the stock solution used by them did not lose in activity to an appreciable extent in a year. However, the above results for the dilute invertase suggest that the stock solutions may have lost in activity also. In Table

<sup>10</sup> Expts. 105 and 106 are compared with 96 and 98 since the same buffer was used in all.

<sup>11</sup> Table V.

<sup>12</sup> Hudson and Paine, *THIS JOURNAL*, 32, 774 (1910).

VIII are collected the results of several experiments on the activity of Invertases 3A and 8 over a period of more than 3 months. The procedure in these experiments was like that of the experiments of Table II. It is shown that these stock solutions lose slowly in activity. The more stable invertase preparations change more slowly than the less stable ones. The decrease in activity in Invertase 3A is a little more than half the rate at which the dilute solution which was kept in the ice-box changed. In the case of Invertase 8 the stock solution changed much more slowly than the dilute solution.

TABLE VIII.

Activity of Stock Invertase Solutions.

Procedure as given in Table II.

152	8	Nov. 18	3	4.3	-0.98	14.03

In using an invertase solution care should be taken to make a complete series of experiments in as short a time as possible and to measure the activity of the invertase at least at the beginning and end of the series if the series is long. Furthermore, considering also the previous action, it follows that if it is necessary to dilute a stock solution, it should be freshly diluted just previous to using.

In making up Tables I to VII only the results of experiments with any one invertase which were made within such time limits that the deterioration meanwhile was negligible were included in any one section of a table.

### Experimental Details.

**Measurement of the Initial Rotation.**—In using invertase inactivated by boiling to make blank determinations of the initial rotation the assumption is made that boiled invertase has practically the same specific rotation as the active invertase. Therefore the optical rotation was determined of boiled and unboiled portions of the invertase preparations used in this investigation. Five-cc. portions of Invertases 3A and 8 and a 10-cc. portion of Invertase 2 were made up to 100 cc. with water. Twenty-five-cc. samples were taken and run into 25 cc. of water and 10 cc. of 0.01 *M* sodium carbonate solution, this procedure being similar to that of the actual experiments except that the sugar was omitted. A portion of the 100 cc. of dilute invertase solution was brought to the boiling point and allowed to cool and the sampling repeated. The optical rotations of the solutions so prepared were determined, and found to be 0.05, 0.02 and 0.12 for the active Invertases 3A, 8 and 2 respectively, and 0.05, 0.03, 0.12 for the inactive

invertases, respectively. Invertase inactivated by boiling evidently has for practical purposes the same specific rotation as active invertase. It is also shown that a separate blank determination must be made for each invertase preparation.

Blank determinations to apply to the above experiments were made as follows. Sugar solutions were prepared containing 5 g. of sucrose and 21.9 cc. of water, or water and buffer as noted below. Five-cc. portions of Invertases 3A and 8 or 10-cc. portions of Invertase 2 were diluted with water and heated to boiling. The invertase solutions were allowed to cool, made up to 100 cc. and 25-cc. portions were added to the sugar solutions as in the actual experiments. Twenty-five-cc. samples were then run into 5-cc. portions of 0.1 *M* sodium carbonate solution and the optical rotations determined. In the experiments using Invertase 3A two different sucrose preparations were used, the first in Expts. 6 to 52 and the second in the experiments numbered higher than 52. Blank determinations of the initial rotation were made for Invertase 3A with both. The second sucrose preparation was used in the experiments with the other invertase preparations. The initial rotations were as follows:

A. Invertase 3A.

Sucrose No.....	1	1	1	1	2	2
Buffer, cc.....	5	5	..	...	5	5
0.005 <i>M</i> H <sub>2</sub> SO <sub>4</sub> , cc. ...	...	...	0.3	0.3	...	...
Rotation.....	13.06	13.06	13.06	13.07	13.07	13.07

B. Invertase 8.

Rotation.....	13.05	13.05
---------------	-------	-------

C. Invertase 2.

Rotation.....	13.12	13.13
---------------	-------	-------

The initial rotation for the experiments like those of Table IV was determined for Invertase 3A using the same procedure as in actual experiments but with inactive invertase. It was found to be 13.06° which is 0.01° lower than with the above procedure. Since 0.01° is about the limit of accuracy in reading the polariscope the initial rotations in the case of the experiments of Table VII were taken as the same as those given in B and C above.

**Determination of the Change in Rotation.**—The invertase solution was added to the sugar solution by means of a calibrated pipet and the time of the start of the reaction considered as the mean time of delivery. The reaction was allowed to proceed for 2 hours and then a 25-cc. sample was withdrawn and run into 5-cc. of 0.01 *M* sodium carbonate solution<sup>13</sup> at a time such that the mean time of delivery would be exactly 2 hours after the start of the reaction. The rotation of the sample was determined after at least 10 minutes and before it had stood 2 hours, by means of a Schmidt and Haensch polariscope which could be set and read to about 0.01°. Light from a mercury-vapor lamp filtered by a Wratten No. 74 filter was used for the polariscopic measurements. The temperature of the sample was maintained at 25° during the determination of the rotation by means of the thermostat described by Nelson and Beegle.<sup>14</sup> The zero point of the polariscope was determined at least once on each day on which determinations were made, using one of the polariscope tubes filled with distilled water. The cover glasses were tested occasionally by turning the tubes while making readings but no optical rotation was ever observed in the 4 cover glasses used throughout this investigation.

**Preparation of the Invertase.**—Invertase 3 and Invertase 8 were prepared in this laboratory by Mr. D. I. Hitchcock and Invertase 2 by Dr. H. L. Simons, the author being indebted to both for the invertase used in this investigation. Nos. 2 and 3 were prepared from autolysed yeast which had been standing for several years. No. 8 was

<sup>13</sup> Hudson, *THIS JOURNAL*, 30, 1564 (1908).

<sup>14</sup> Nelson and Beegle, *ibid.*, 41, 559 (1919).

prepared from fresh yeast. Autolysis, precipitation of the proteins and dialysis were carried out as described by Nelson and Born.<sup>15</sup> The invertase was however not precipitated from the dialyzed solutions, the latter being used as the "stock solutions." Invertase 3A was a small portion of Invertase 3 which was removed and kept in a smaller bottle for convenience. The apparent difference in activity between the two may have been due to deterioration during the time that elapsed between the experiments with Invertase 3 and those with 3A. All stock solutions were kept in an ice-box.

**Preparation of the Sucrose.**—Rock candy known to have been made from the best commercial sucrose was dissolved and reprecipitated by addition of alcohol as described by Cohen and Commelin.<sup>16</sup> It was dried over conc. sulfuric acid at about 50° and preserved in glass-stoppered bottles sealed with paraffin.

**Preparation of the Buffers.**—Buffers 1 and 3 were prepared by adding 197 cc. of 0.1 *M* hydrochloric acid to 303 cc. of secondary sodium citrate freshly prepared as described by Sorensen.<sup>17</sup> Buffer No. 2 was prepared similarly using a citrate solution prepared from *N* sodium hydroxide solution which had stood for some time and had dissolved some silica from the bottle. The acetate buffer was prepared by adding 655 cc. of 0.1 *M* acetic acid to 345 cc. of 0.1 *N* sodium acetate.

Experiments similar to those of Table II with Invertase 3A using the different buffer solutions are shown in Table IX. The slight amount of impurity in buffer No. 2 was found to have an appreciable effect on the velocity of hydrolysis. Expts. 117 and 118 show that the velocity when buffer No. 2 is used is less than when No. 3 is used. The apparent difference between the effects of Buffers 1 and 3 on the velocity of hydrolysis can be explained by deterioration of the invertase during the time between Expts. 70 and 118.

The acetate buffer gives a velocity of hydrolysis which is a little less than that when a citrate buffer is used as Expts. 70, 71 and 72 in Table IX and 60, 61, 78 and 83 in Table IV show.

TABLE IX.

Effect of Different Buffers on the Activity of Invertase.

Procedure as in the experiments of Table II.

Expt.	Buffer.	Date, Aug.	Conc. H <sup>+</sup> × 10 <sup>3</sup> .	Rotation after 2 hrs.	Change in 2 hrs.
40	Citrate No. 1	2	4.1	0.34	12.72
70		10	4.0	0.31	12.76
95		19	3.8	0.52	12.55
107		23	4.3	0.49	12.58
117		26	4.3	0.59	12.48
118	Acetate	26	4.3	0.41	12.66
71		10	4.3	0.40	12.67
72		10	4.5	0.36	12.71

The differences in the effect of the different citrate buffers on Invertase 8 are shown in Table V to be very small. Here again the difference between a stable and an unstable invertase preparation is noticeable, the former being preferable.

### Summary.

1. Invertase solutions are subject to loss in activity when diluted. The loss varies with the substances present in the water with which the invertase is diluted.

<sup>15</sup> Nelson and Born, *THIS JOURNAL*, 36, 393 (1914).

<sup>16</sup> Cohen and Commelin, *Z. physik. Chem.*, 64, 1 (1908).

<sup>17</sup> Sorensen, *Biochem. Z.*, 21, 131 (1909).

2. Dilution with distilled water is attended by less loss than is the case in dilution with very weak acids, and is reproducible for practical purposes if the dilution is not too great.

3. When an invertase solution is added to a solution containing sucrose, losses in activity due to dilution are less than when the invertase is diluted by a similar solution not containing sucrose.

4. The velocity of hydrolysis of sucrose by invertase is greater when a citrate buffer or acetate buffer is used as the source of hydrogen ions than when citric or acetic acid respectively is so used.

5. With different invertase preparations the magnitude of the losses in activity on dilution varies. Invertase solutions may be designated as more or less stable according to the magnitude of such losses in activity.

6. Both dilute and stock solutions of invertase lose strength on standing, the former faster than the latter. Stock solutions of the more stable invertase preparations lose activity more slowly than stock solutions of the less stable invertase preparations.

## ADDITION REACTIONS OF THE CARBONYL GROUP INVOLVING THE INCREASE IN VALENCE OF A SINGLE ATOM.

By JAMES B. CONANT.

Received April 29, 1921.

The addition reactions of the phosphorus halides, which have been described in previous papers,<sup>1</sup> are of a different type from the usual addition reactions of simple or conjugated carbonyl compounds. They involve the formation of a cyclic compound by reason of the increase in valence of a single atom, while in most addition reactions of carbonyl compounds the reagent seems to have dissociated into two parts which subsequently become attached to the carbon and oxygen atoms. The Grignard reagent, hydrocyanic acid, and sodium bisulfite may be mentioned as common examples of this usual type of reaction.

These common reagents react with  $\alpha,\beta$  unsaturated ketones and aldehydes in much the same manner. When they combine with the conjugated system, the two parts of the addendum attach themselves in the 1,4 position to the oxygen and carbon atoms. The molecule of the reagent apparently undergoes cleavage into the same fragments in the case of both 1,2 and 1,4 additions.

<sup>1</sup> THIS JOURNAL, 39, 2679 (1917); 42, 830, 2337 (1920); 43, 1665, 1667 (1921).

The 1,4 addition of phosphenyl chloride and the 1,2 and 1,4 additions of phosphorus trichloride do not fit into this classification; they seem to be examples of another sort of addition reaction. In these cases the addendum unites with the carbonyl group or conjugated system *without cleavage* and the phosphorus atom increases its apparent valence by two. The reaction is reversible.

Such reactions involving the increase in valence of a single atom have been found to take place with a variety of simple carbonyl compounds, and also with unsaturated ketones. The phosphorus halide, also, may be varied. As shown in the experimental portion of this article, phosphorus tribromide readily adds in the 1,4 position to benzal-acetophenone. The equilibrium is more in favor of the addition product than with the trichloride. Several instances of the 1,4 addition of phosphenyl chloride have already been investigated and unpublished results obtained in this laboratory have shown that diphenoxy-chlorophosphine, monophenoxy-dichlorophosphine and diethoxy-dichlorophosphine behave in a similar manner. The reaction is thus general enough to warrant consideration from a theoretical standpoint.

Reactions of this special type are common in inorganic chemistry; for example, the reaction between ammonia and the halogen acids or between the trivalent phosphorus halides and chlorine. These reactions take place with the increase of valence of a single atom, and are for the most part reversible. The work of Werner and others provided a starting point for an interpretation of pentavalent nitrogen compounds, and the theory of the cubical atom as developed by G. N. Lewis<sup>2</sup> and later by Langmuir<sup>3</sup> has provided a satisfactory picture of the changes of valence of the elements in the fifth group of the periodic table. An application of this view has been helpful in the investigations just discussed and a further expansion of it leads to a general hypothesis in regard to most reactions of carbonyl compounds.

### The Change from a Covalence of Three to a Covalence of Four.

According to Lewis' theory the three hydrogen atoms in ammonia are held to the nitrogen by the sharing of pairs of electrons of a group of eight. In ammonium chloride the four hydrogen atoms are likewise held by the sharing of electrons but the chlorine atom is not directly bound to the nitrogen; it is a negatively charged atom, and in solid ammonium chloride is held with the positively charged ammonium radical in a certain

<sup>2</sup> Lewis, *THIS JOURNAL*, 38, 762 (1916).

<sup>3</sup> Langmuir, *ibid.*, 41, 868 (1919).

spatial arrangement by electrostatic forces. In solution both ions are free to move about. The linkage of hydrogen to nitrogen is a non-polar bond, (usually referred to as valence in organic chemistry); the chlorine atom is held by a polar bond (what is usually meant by valence in the chemistry of electrolytes). Similarly it seems probable that in phosphorus pentachloride, four chlorine atoms are held by non-polar bonds, and one by a polar bond. This is often represented thus:  $[(\text{PCl}_4) + \text{Cl}^-]$ .

The mechanism by which the non-polar valence (the covalence) of nitrogen and phosphorus in such compounds increases from three to four has been but little discussed. It involves the attachment of a positively charged atom or group by means of the two unshared electrons of the tri-valent atom. In aqueous solution it is probably the hydrogen ion which is thus attracted. To explain the reaction in non-aqueous solutions or the addition of such non-electrolytes as methyl iodide to  $\text{RNH}_2$  or chlorine phosphorus trichloride, one may either posit the existence of ions, or conceive of molecules in which one pair of electrons is pulled toward one atom to such an extent that the positive nucleus of the other is exposed. Lewis<sup>2</sup> has already pointed out these alternatives in the case of the halogens; there is some evidence which points to the existence of positive and negative halogen ions. Until more is known about this "ionization" of essentially non-polar substances no clear line can be drawn between the two cases. The addition reactions of inorganic chemistry, of the type under consideration, seem to depend on the attraction of the positive nucleus of some ion or "partially ionized" molecule, and the resulting formation of a polar compound;

From the same point of view the carbon atom of the carbonyl group may act as if it were a positively charged ion. The positive nucleus of the carbon atom is more exposed in such compounds than in saturated compounds because of the drawing away of the two electrons which are shared with the oxygen octet. The *positively charged nucleus* will attract the unshared electrons of the central atom of such compounds as ammonia or phosphorus trichloride. When the molecules are drawn sufficiently close together an addition compound will be formed. The oxygen atom of this compound will be negatively charged, the nitrogen or phosphorus atom positively charged. The polar bond corresponding to the chloride ion of ammonium chloride will then be an "inner polar bond" such as exists in the amino acids;

transformed<sup>4</sup> to  $R_2CHOHPO(OH)_2$ . Similarly, as described in earlier papers, the 1,4 addition compound reacts with acetic anhydride producing a cyclic anhydride; with acetic acid an open chain phosphonic acid is formed.

This great reactivity of the chlorine atoms attached to the pentavalent phosphorus atom of the addition compound, is of great practical importance in carrying out all these addition reactions. It is possible to cause the reversible addition reactions to go to completion if cold acetic acid or acetic anhydride is used as a medium; if the proper temperature is maintained only the addition product will act with the acetic acid or anhydride. Very good yields of phosphonic acids (or their cyclic anhydrides) can thus be obtained from equimolecular amounts of phosphorus halide and unsaturated compound. However, in the initial addition reaction only about 30% of the two substances have combined as can be shown by rapidly decomposing the mixture with water, (see experimental part).

### Reactions of Nitrogen Compounds.

In the case of the addition compounds of aldehydes with ammonia and substituted ammonias, such as hydroxylamine and phenylhydrazine, the initial product cannot rearrange in the same manner as the phosphorus trichloride addition product. Such a rearrangement would involve the formation of a negative hydrogen ion, which is obviously impossible. Rearrangement may take place, however, so that a hydrogen atom shifts to the oxygen atom, or water may be eliminated from the molecule forming an unsaturated compound (such as an oxime or phenyl hydrazone);

If neither of these possibilities can occur no stable addition product can be isolated as the initial reaction is easily reversible, and stops at some equilibrium point. However, in certain cases it may be that a compound of the inner salt type can be stable without rearrangement. E. A. Werner,<sup>5</sup>

or example, believes the formula for urea to be  $NH = \overset{\overset{O^-}{\diagup}}{\underset{\diagdown}{C}} NH_3^+$  and

<sup>4</sup> THIS JOURNAL, 42, 2337 (1920).

<sup>5</sup> Werner, *J. Chem. Soc.*, 113, 84 (1918).

writes the reaction for its formation from cyanic acid and ammonia as

This is, of course, exactly the type of reaction we are here considering, and if Werner is correct in the interpretation of his experiments, the addition of ammonia to cyanic acid is another case of an addition reaction of a carbonyl group which involves the increase in covalence of the addendum.

From this point of view, the great reactivity of trivalent nitrogen compounds towards aldehydes and ketones is due to the *attraction of the unshared pair of electrons on the nitrogen atom by the "exposed" nucleus of the carbon atom of the carbonyl group*. It is exactly this attraction of the unshared electrons by the positive nucleus of the hydrogen ion which makes these same compounds weak bases. The two phenomena are thus parallel.

### The Hypothesis Applied to Other Reactions.

Many reactions which do not seem to involve the increase in valence of a single atom may also be interpreted by this hypothesis. Recent investigations<sup>6</sup> seem to indicate that the Grignard reagent acts as if it were at least partially ionized; for example, into  $\text{CH}_3^-$  and  $\text{MgI}^+$ . Such a negative ion would be attracted by the positive carbon atom of the carbonyl group; the product would be the salt of a very weak acid (the carbinol) which on treatment with water or acid would yield the hydrogen compound;

Phosphorus pentachloride is another somewhat different reagent. Here the negative chlorine is attracted and the positive  $\text{PCl}_4$  group is held to the resulting complex by a polar bond. Such a compound might undergo an irreversible intramolecular change with the formation of  $\text{POCl}_3$  and a dichloride;

<sup>6</sup> THIS JOURNAL, 39, 82 (1917).

equilibrium of the initial reaction but on the speeds of the subsequent reactions. By analogy with certain inorganic substances and reactions it has been possible to formulate roughly some of these factors in the case of the action of the phosphorus halides. Until more quantitative evidence is at hand it will not be profitable to discuss the influence of various groups on the course of such reactions, although eventually this hypothesis should be useful in correlating many of the facts concerning the so-called "reactivity" of carbonyl compounds.

The reactions of ethylene oxides<sup>7</sup> are readily formulated by means of this same hypothesis. The electrons of the carbon atoms are drawn away in the formation of a three-membered ring leaving the positive nucleus of the carbon atoms exposed. The force fields of these carbon nuclei would attract the same sort of molecules as in the case of carbonyl compounds. The resulting substances could undergo the same sort of rearrangement; for example with ammonia;

This electronic interpretation of the facts summarized by Baeyer's strain theory has already been pointed out by Langmuir. In larger rings the electrons are drawn away to a less extent and four-, five- and six-membered rings are therefore less reactive.

In conclusion the writer wishes to express his great indebtedness to Dr. E. Q. Adams of the Bureau of Chemistry for having pointed out to him in 1917 the possibility of applying Professor Lewis' ideas to the addition reactions of phosphorus trichloride and to similar problems in organic chemistry.

### Experimental.

**The Equilibrium between Phosphorus Trichloride and Benzal-acetophenone.**—The addition reaction between benzaldehyde and phosphorus trichloride has already been shown<sup>8</sup> to be reversible; a definite equilibrium point is reached and the determination of this equilibrium has shown that the reaction follows the usual law of mass action. The method used in that case was to decompose the reaction mixture with water and determine the amount of phosphorus acid formed by the hydrolysis of the uncombined trichloride. Both the addition product and the trichloride react so rapidly with water that little if any shifting of the equilibrium takes place during hydrolysis. The results obtained showed that when

<sup>7</sup> The action of the phosphorus halides on such compounds is being investigated.

<sup>8</sup> *THIS JOURNAL*, 42, 2337 (1920).

equimolecular amounts of benzaldehyde and phosphorus trichloride are brought together, equilibrium is obtained when 30% of the material has combined.

It was of interest to obtain some similar values for the 1,4 addition of phosphorus trichloride. This was done in a rough way by determining the amount of phosphonic acid formed (which is insoluble in water) and the amount of ketone left unchanged when the reaction mixture was decomposed with water. The procedure was as follows.

Five g. of benzal-acetophenone, 0.024 g. mol. (carefully dried in a vacuum over phosphorus pentoxide), and 3.4 g. of phosphorus trichloride (0.025 g. mol.) were mixed together in a glass tube which was then sealed. The solid ketone soon dissolved almost completely in the trichloride. The mixture was allowed to stand for a definite time at room temperature (25°). The tube was then opened and the contents quickly stirred into 250 cc. of water. The water solution was carefully extracted with ether and the phosphonic acid then removed from the ethereal layer by extraction with sodium hydroxide. Evaporation of the ether yielded the unchanged ketone. The phosphonic acid was obtained by acidifying the sodium hydroxide solution and extracting with ether. The amount of recovered ketone and phosphonic acid in every case accounted for at least 95% of the original material. The following results were obtained.

Hours.	Acid g.	Ketone equivalent.	Per cent. reacted.
1	1.5	1.1	22
2	1.6	1.2	24
3	1.5	1.1	22
1 (4 mols $\text{PCl}_3$ )	3.2	2.3	46

These figures while only approximate show that the reaction comes to a definite equilibrium in a comparatively short time. When a large excess of one of the materials is employed (last experiment) more addition product is formed. The recovered ketone and phosphonic acid were both very pure as shown by their sharp melting points: this is evidence that no side reactions are appreciable in this length of time. When the components are left in contact for many days, however, other reactions take place; the acid material becomes impure and the non-acid material is no longer unchanged ketone but some oily substance.

**The Addition of Phosphorus Tribromide to Benzal-acetophenone.**—Phosphorus tribromide combines with benzal-acetophenone even more readily than the trichloride. The reaction was investigated by bringing the materials together and after a given time decomposing with water as described in the experiment with the trichloride. In this case, however,  $\beta$ -bromobenzyl-acetophenone was obtained as the non-acid material instead of the unchanged ketone. This was probably due to the addition of hydrobromic acid to the unsaturated ketone during the decomposition of the mixture with water; an oily mass is at first formed which it takes some minutes to decompose completely by agitating with water. When the reaction mixture was poured into dil. sodium hydroxide solution instead of water, most of the non-acid material was unchanged ketone.

The following results were obtained with equimolecular quantities.

Hours.	Acid g.	Ketone equivalent.	Per cent. reacted.
1	3.7	2.6	52
1	3.2	2.2	44
2	3.6	2.5	50
4	3.6	2.5	50

It is evident that the equilibrium is much more in favor of the addition product with phosphorus tribromide than with phosphorus trichloride.

**Reaction in Acetic Acid.**—5 g. of benzal-acetophenone was mixed with 6.8 g. of phosphorus tri-bromide (10% excess) and 7 g. of acetic acid. The ketone dissolved and the reaction mixture then became quite warm while fumes of acetyl bromide were apparent. After standing for 3 hours the mixture was poured into water and the materials were separated in the usual way. 6.2 g. of pure phosphonic acid was obtained (88%) and 0.5 g. of unchanged ketone.

### Summary.

1. The addition reactions of the phosphorus halides with carbonyl compounds are of a different type from the reactions of most reagents with these substances. They involve the formation of a cyclic compound with the increase in valence of a single atom while the more usual reactions take place with the cleavage of the reagent into two parts. The reaction is reversible.

2. This new type of reaction is analogous to addition reactions of inorganic chemistry such as the addition of the halogen acids to ammonia.

3. Lewis' theory of the cubical atom has been applied to this problem. The positive nucleus of the carbon atom of the carbonyl group is exposed by the drawing away of the electrons of the double bond. This exposed nucleus behaves in addition reactions like a positively charged atom and unites with atoms having unshared electrons (the phosphorus atom in the trichloride and the nitrogen atom in ammonia).

4. The resulting addition compounds may undergo various irreversible intramolecular changes or react irreversibly with other reagents. In such cases stable products will be formed.

5. This hypothesis is applied to the 1,2 and 1,4 addition of phosphorus halides, ammonia and its derivatives, the Grignard reagent and phosphorus pentachloride. The reactions of ethylene oxide are also considered.

6. Phosphorus tribromide combines with benzal-acetophenone in the 1,4-position, the reaction being parallel to that with the trichloride. The equilibrium has been measured for both substances; it is more in favor of the addition product in the case of the tribromide than with the trichloride.

THE ELIMINATION OF HYDROGEN CHLORIDE FROM CHLORO-HYDROCARBONS.<sup>1</sup>By W. F. FARAGHER<sup>2</sup> AND F. H. GARNER.<sup>3</sup>

Received May 9, 1921.

The preparation of unsaturated compounds from aliphatic chloro compounds by the action of high temperatures was investigated by Nef.<sup>4</sup> His work, which was limited to ethyl, propyl, and *isobutyl* halides showed that ethyl chloride was completely dissociated into ethylene and hydrogen chloride at a temperature of 550°, propyl and *isobutyl* chlorides being completely converted in an analogous manner at 500°. The contact materials used by Nef were pumice stone and soda-lime.

Sabatier and Mailhe<sup>5</sup> in 1904 succeeded in preparing alkylenes from the corresponding aliphatic monochlorides by using as catalysts the chlorides of the divalent metals (Ni, Co, Fe, Cd, Pb, Ba, etc.) at 260°. By this method ethyl, propyl, *isobutyl* and *iso-amyl* chlorides when passed over barium chloride gave the corresponding olefins. At the same time the barium chloride used became gray in color owing to the simultaneous polymerization of a small proportion of the olefins formed. These authors found that the chlorides of monovalent elements exerted no catalytic action even at 350°.

Alumina was found by Senderens<sup>6</sup> to remove hydrogen chloride from propyl and *isobutyl* chlorides at 250°, whereas with no catalyst present *isobutyl* chloride was quite stable at 430°.

At 350°, propyl and *isobutyl* chlorides gave, with alumina as catalyst, yields of 97% of propylene and 95% of *isobutylene* respectively.

The cleavage of hydrogen chloride from mono- and dichloro-cyclohexanes by the use of the catalysts recommended by the above authors has been patented by the Badische Anilin-u. Soda Fabrik in a series of patents: U. S. patent 1,221,382 (1917); Brit. patent 5,429 (1912); and Ger. patents 254,473 and 255,538 (1913). The preparation of isoprene and similar diolefins from chlorinated derivatives of pentane and hexane under reduced pressure using alumina and barium chloride as catalysts has also been patented by this firm (French patents 435,312 and 434,586 (1911), Brit. patents 10,826 and 18,356 (1911) and Ger. patent 255,519).

The present investigation was undertaken with chlorine compounds of hexane, heptane, and cyclohexane in order to determine the most suitable conditions for the preparation of unsaturated compounds therefrom. It was also desired to ascertain the relative stability of dichloro- and monochloro compounds with various catalysts at the high temperatures involved in these dechlorinations. As the cleavage of these chlorides into hydrogen chloride and olefins or diolefins is always accompanied by a complete decomposition of a portion of the hydrocarbons formed, it is obvious that the catalyst must lose some of its effect as the reaction is prolonged owing to the deposition of carbon. This question was investigated by finding the change in catalytic activity as the same catalyst was used continuously for dechlorination.

Hexane, *isohexanes* and heptane fractions were isolated from Pennsylvania straight-run gasoline by repeated fractionations; aromatic hydrocarbons were removed by means of a sulfuric-nitric acid mixture and the fractions redistilled several times through a 120 cm. Hempel column filled with magnesium turnings, and covered with asbestos paper; thus the fractions finally obtained were nearly pure hexane and heptane. Fractions 61° to 64°, 67.5° to 70°, and 97° to 100°, (all at 760 mm.) were collected, representing a mixture of *isohexanes*, *n*-hexane, and *n*-heptane respectively.

Cyclohexane obtained from the Dayton-Wright Division of the General Motors Corporation was carefully freed from benzene and refractionated twice, the fraction of boiling point 79° to 79.5° (740 mm.) being collected; the cyclohexane used for the preparation of chloro compounds melted at 4.5°. The product, therefore, was practically pure cyclohexane.

The paraffin hydrocarbons contained small amounts of polymethylenes as a result of their source and method of preparation. Owing to the comparatively large amounts required for this investigation, however, it was considered that the only practicable method was to isolate from a suitable gasoline all of the paraffin hydrocarbons required.

**Chlorination.**—Cyclohexane was chlorinated in the manner briefly described by Sabatier and Mailhe.<sup>7</sup> By the chlorination of 300 g. of cyclohexane at a temperature of 20° to 25° until an increase in weight of 50 to 75% of that theoretically required for the production of monochloro-cyclohexane was realized, the following products were obtained after several fractionations.

	G.
Cyclohexane recovered unchanged.....	40
Fraction 139–144°, monochloro-cyclohexane ( $d_4^{20}$ 1.002).....	150
Fraction 75–85° (15 mm.), dichloro-cyclohexane ( $d_4^{20}$ 1.179).....	105
Fraction 95–105° (15 mm.), trichloro-cyclohexane ( $d_4^{20}$ 1.266).....	24
Intermediate fractions and residue.....	50

<sup>7</sup> Sabatier and Mailhe, *Compt. rend.*, 137, 240 (1903).

The dichloro- and trichloro-cyclohexanes were purified by two distillations at a pressure of 15 mm.

Hexane and *isohexane* were chlorinated in the vapor phase as first suggested by Schorlemmer<sup>8</sup> and also employed by Michael and Turner.<sup>9</sup> In our procedure, chlorine was introduced at about the middle point of a tube through which the hydrocarbon was being refluxed. A thermometer was inserted at the position where the chlorine was introduced and by this arrangement the course of the chlorination was followed closely.

By this method monochloro derivatives were the principal products and very small amounts of dichloro and more highly chlorinated compounds were formed. It was, however, essential that this chlorination be carried out in diffused light, as in full daylight a flame appears and carbon is formed. In order to obtain quantitative yields it is necessary to resort to absorption or very efficient cooling of the issuing hydrogen chloride, as otherwise some of the chlorinated products will be carried away with it and thus be lost.

The chlorinated products were washed with dil. alkali and water to free them from hydrochloric acid. With some of the chlorinated compounds it was necessary to use brine instead of water owing to the fact that the specific gravities of the compounds were very close to that of water.

A fraction distilling from 120° to 124° which was obtained from the chlorinated *n*-hexane after 4 fractionations, corresponds to 2-chloro-*n*-hexane.

Similarly, from the *isohexane* a fraction distilling from 119° to 123° was isolated. This fraction was a mixture of monochloro-hexanes.

Heptane was chlorinated in a way similar to that used with cyclohexane as already described.

Dichloro-heptanes constituting the fractions boiling from 90 to 100° (15 mm.) and monochloro-heptane forming the fraction 150 to 160° (760 mm.) were obtained after three fractionations.

The specific gravities and iodine numbers of these chloro compounds were determined. The iodine numbers of the chloro compounds were in all cases very small and in all probability were due to the presence of small amounts of olefins.

**Dechlorination.**—In the dechlorination process the chloro compounds were passed at the desired temperature through a glass tube which contained the catalyst. The products of the reaction were then led through a tube containing soda-lime maintained at a temperature of 100° or of 150° and were passed finally into a receiver cooled by an ice-bath. The purpose of the heated soda-lime tube was to remove hydrogen chloride and

<sup>8</sup> Schorlemmer, *Phil. Trans.*, 163, 111 (1872).

<sup>9</sup> Michael and Turner, *Ber.*, 39, 2154 (1906).

thus to prevent its recombination with the olefin. (This reaction was shown by Nef<sup>4</sup> to occur with butylene.) By this means the product obtained by condensation really indicates the true effect of the catalyst. The chloro compound was contained in a buret connected to the tube containing the catalyst through a 2-way glass stopcock; a stream of dry nitrogen could thus be passed through the catalyst when desired. The tube containing the catalyst was heated at 150 to 500° as desired by means of an electric resistance-furnace, the temperature being controlled by a rheostat. The length of the catalyst tube was 70 cm. The soda-lime tube, also, was heated in a similar manner. The temperatures of both the catalyst tube and the soda-lime tube were measured by means of iron-constantan thermocouples. Condensation of the vapors was effected by a tube, surrounded by an ice-bath, which extended into a test-tube with side arm. The side arm was connected to a train of bromine absorption tubes cooled in ice and the latter to a gasometer when desired. The temperature of the soda-lime tube was kept sufficiently high to prevent any of the chloro compound from condensing in this tube, but not high enough for its catalytic effect in the reaction to be measurable. The rate at which the chloro compound was introduced into the tube containing the catalyst could be regulated, with practice to any desired value. The compound was, in general, immediately vaporised owing to the high temperature of the catalyst. After the desired amount of chloro compound had been passed through the tube, the vapors remaining in the tube were driven out by means of a stream of dry nitrogen introduced through the 2-way stopcock and were condensed in the ice-water condenser.

From the percentage of liquid condensed, the yield of dechlorinated product was calculated; see, for example, Table III. The specific gravity and iodine numbers of this condensate indicate the proportion of unsaturated compounds formed, since the iodine number of the unsaturated compound is known. The iodine number serves as an index to the amount of unsaturation only in the case of olefins; in the case of diolefins the iodine value obtained is far below that corresponding to the true extent of the unsaturation. This point will be covered fully in a later paper. The iodine numbers were determined by Hanus method, giving half-hour contact with the iodine solution in the dark (0.10 g. of olefin to 25 cc. of Hanus solution).<sup>10</sup>

The bromine collected any unsaturated compounds which were not condensed by the ice-bath and from the amount of gas evolved during the

<sup>10</sup> It was thought unnecessary to make chlorine determinations on the condensates since a consideration of the specific gravity, iodine number, and distillation characteristics furnishes a sufficiently accurate index to their composition. Owing to the great differences between the boiling points of the chloro compounds and the olefins obtained from them, an analysis by fractionation shows the extent to which the elimination of hydrogen chloride has been effected.

time the liquid was being introduced into the catalyst tube, the extent of decomposition occurring could be ascertained.

The following contact materials were used as catalysts in the dechlorination process: unglazed porcelain, unglazed porcelain which had been soaked in a strong solution of barium chloride and then dried, and alumina (commercial aluminum hydroxide worked to a plastic mass with water, and then dried at the temperature at which it was used); Pyrex glass was used in some experiments since any effect glass may have in the course of the reaction is due presumably to surface action only.

The experiments carried out with the Pyrex glass should, therefore, indicate only the effect of variation of the temperature on the reaction.

**Dependence of Dechlorination on Rate of Introduction of Chloro Compound.**—Experiments were made with monochloro-*isohexane* to determine the effect of varying the rate at which the chloro compound was passed over the catalyst on the amounts of hydrogen chloride removed. These experiments were carried out at 200°, 300°, and 400°, using unglazed porcelain as the catalyst. The soda-lime tube was maintained at 150° during these experiments.

TABLE I.  
IODINE NUMBERS OF CONDENSATES FROM MONOCHLORO-*ISOHEXANE*.  
Iodine number of *isohexene* = 302 (calc.).

Temperature of catalyst, ° C.	Time, Min.	10 cc. passed over catalyst in			
		15.	30.	60.	120.
200	228	209	243	252	
300	246	216	275	290	
400	253	271	263	292	

In general, the iodine numbers and specific gravities of the condensates were in agreement (see, for example, Table III), *i. e.*, the higher the iodine number the lower is the specific gravity.

From these experiments it will be observed that as the rate of introducing the chloro-*isohexane* is lowered, the dechlorination proceeds more completely, but the effect produced by the difference between the two rates, 10 cc. in 15 minutes and 10 cc. in 2 hours, is not very great, inasmuch as fairly complete dechlorination is effected even at 200° by passing 10 cc. over the catalyst in 15 minutes.

It will also be noticed that the effect of temperature from 200° to 400° is not very marked in the preparation of *isohexylene* from chloro-*isohexane*.

As a result of the experiments described in Table I, it was decided to adopt the uniform rate of 20 cc. in one hour for passing the chloro compound over the catalyst in all the experiments described later.

**Loss of Catalytic Power on Prolonged Use.**—These experiments were carried out to determine the effect on the catalytic activity of unglazed

Thus again unglazed porcelain alone acted as a more efficient catalyst than unglazed porcelain impregnated with barium chloride. It will be noted that the dechlorination did not proceed as readily in this case and that apparently a higher temperature is necessary with the dichloro compound than with the monochloro compound. Decomposition of the hydrocarbons also occurred to a greater extent than was the case with the monosubstituted chloro compounds.

TABLE VI.  
CHLORO-HEPTANE;  $d_{40}^{20}$  0.914.  
Iodine Number of Heptylene = 260. (Calc.).  
Iodine Number of Condensates Using Various Catalysts.

Temperature of catalyst. ° C.	Unglazed Porcelain.	Alumina.	Unglazed porcelain barium chloride.	Pyrex glass.
150	100	...	...	...
200	127	198	178	52.5
250	192	238	187	64
300	260	254	170	83
400	265	250	180	181

Alumina is the most active catalyst up to 250° but of all the catalysts used it apparently lost its catalytic effect most rapidly as the result of carbonization. Pyrex glass is inferior to all of the other contact materials in promoting dechlorination at these temperatures and probably brings out only the influence of temperature on the reaction.

From the condensates obtained in these experiments, the olefins were readily separated by fractionation.

Thus, from 70 cc. of chloroheptane condensate the fractions described in Table VII were obtained. It will be noted that Fraction 90 to 110° has an iodine number close to that of heptylene.

TABLE VII.			
Boiling Point. ° C.	Volume. Cc.	$d_{40}^{20}$ .	Iodine Number.
90-110	37	0.744	237
110-145	14	0.823	157
145-155	13	0.903	53

TABLE VIII.  
DICHLORO HEPTANE;  $d_{40}^{20}$  1.068.  
Iodine Number of Heptadiene = 518. (calc.).  
Temperature of catalyst. ° C.

Temperature of catalyst. ° C.	Catalyst.	
	Unglazed porcelain.	Alumina.
200	163	181
300	170	173
350	194	126
400	216	114

Here again it will be noted that alumina is more effective at low temperatures than unglazed porcelain but that its catalytic activity *decreases*

with rise in temperature. A number of experiments carried out with chloro derivatives of cyclohexane, proved that these compounds split off hydrogen chloride more readily than the corresponding aliphatic compounds.

TABLE IX.

Monochloro-cyclohexane; $d_0^{20}$ , 1.003. Iodine Number of Cyclohexene = 310 (calc.).			
Temperature of catalyst. °C.	Unglazed porcelain.	Catalyst alumina.	Pyrex glass.
200	245	260	192
250	275	256	172
300	272	234	214
400	297	152	274

Alumina is the most active catalyst with monochloro-cyclohexane at the lower temperatures; Pyrex glass probably demonstrates again only the influence of temperature in increasing the unsaturation of the product as 400° is approached.

TABLE X.

Dichloro-cyclohexane; $d_0^{20}$ , 1.179. Iodine Number of Dihydro-benzene = 317. (calc.).		
Temperature of catalyst. °C.	Unglazed porcelain.	Alumina.
200	113	132
250	146	167
300	175	170
400	188	117

TABLE XI.

Trichloro-cyclohexane;  $d_0^{20}$ , 1.266.  
Catalyst: Unglazed Porcelain.

Temperature of catalyst. °C.	Specific Gravity.	Benzene. %.
250	1.009	10
350	1.061	..
450	0.984	20

The percentage of benzene was determined by conversion into *m*-dinitrobenzene.

Experiments were also carried out with chlorobenzene, but apparently no dechlorination was produced even at 500°. According to Kramers<sup>11</sup> chlorobenzene is changed slowly into diphenyl and decomposition products at a red heat.

Thus it will be seen that, of the compounds tested, chlorobenzene is the most difficult to decompose and chloro-cyclohexane the most unstable at high temperatures. The condensates obtained from the experiments described above readily gave fairly pure olefins and diolefins on fractiona-

<sup>11</sup> Kramers, *Ann.*, 189, 135 (1877).

tion and this method of removing hydrogen chloride from a chloro compound of a hydrocarbon can be recommended as a general method for the preparation of olefins in the case of monochloro-compounds. In the case of dichloro compounds, the yields of diolefins are small at low temperatures because of poor conversion, while at higher temperatures decomposition of the diolefin produced presumably occurs and there is a poor yield in these cases also.

In the following table are given the properties of some olefins prepared by this method.

TABLE XII.  
Properties of Hydrocarbons.

	Boiling point. °C.	$d_4^{20}$ .	Iodine number.
<i>Isorexene</i> .....	64-65	0.684	294
<i>n</i> -Hexene.....	65-66	0.691	285
<i>n</i> -Heptene.....	97-98	0.727	237
Cyclohexene.....	80-81	0.809	303.5

It is quite unnecessary and useless to prepare a special catalyst for this operation (unless carbonization is prevented by some special method) since the catalyst loses its specific activity after a very short period of service.

### Summary.

1. The chloro compounds of hydrocarbons containing 6 or 7 carbon atoms can be classified in the following order according to the ease with which hydrogen chloride is split off: hydro-aromatic, aliphatic and aromatic.

2. The stability of monochloro compounds of aliphatic hydrocarbons at a given temperature decreases with increasing molecular weight (at least until there are 7 carbon atoms in the chain).

3. There is much more extensive decomposition and greater difficulty in separating all the chlorine from dichloro compounds than from monochloro compounds.

4. Of the three catalysts alumina, unglazed porcelain and unglazed porcelain impregnated with barium chloride, alumina is the most efficient; but all three lose their activity rapidly owing to the "poisoning" produced by the decomposition of the hydrocarbons. (The "poisoning" in these cases is probably a mechanical effect due to the deposition of "carbon" on the catalyst).

5. A method for the preparation of olefins and diolefins from chloro compounds of hydrocarbons has been investigated and the method shown to be quite satisfactory for olefins. With diolefins, secondary decompositions occur and poor yields are obtained.

U. S. DEPARTMENT OF AGRICULTURE.]

## THE ODOROUS CONSTITUENTS OF PEACHES.

BY FREDERICK B. POWER AND VICTOR K. CHESNUT.

Received May 11, 1921.

No information appears to have been recorded hitherto in chemical literature respecting the nature of the substances to which the odor of the peach is due. Although many preparations designated as "Peach Oil" or "Peach Essence" have long been in use for flavoring purposes, it is well known that they consist for the most part of purely empirical mixtures of esters and essential oils with other more specific aromatic substances. The general character of such mixtures also indicates that their components are not such as have actually been found to occur in the fruit whose flavor they are supposed to represent. Inasmuch as the kernels of the peach are sometimes used to impart their particular flavor, which is the same as that of the bitter almond or benzaldehyde, it not infrequently happens that the last mentioned substance is regarded as one of the proper constituents of the peach aroma, but the present investigation has shown that it is not contained in the pulp of the fruit.

### Experimental.

It may be stated in the beginning that throughout this investigation only the fresh pulp of the peach was employed, the pits having been carefully removed. This precaution was naturally of importance in order that the distillate should contain only those odorous substances present in the edible part of the fruit, and to exclude any benzaldehyde which might be produced solely from the pits, especially if broken.

**Special Test for Hydrogen Cyanide.**—It has been stated by Windisch<sup>1</sup> that "all kinds of stone fruits contain in the pulp the elements of hydrocyanic acid. The fruit juices, wines and brandies prepared therefrom, therefore also contain hydrocyanic acid, even when made from the pulp of the fruit with the exclusion of the pits, although in extremely small amount. If the pits are also employed the amount of hydrocyanic acid is considerably increased." In connection with these general observations, reference was particularly made to cherries and plums, although peaches also must naturally be included among the stone-fruits.

A quantity of ripe, free-stone peaches was carefully deprived of the pits, and the pulp, amounting to 5.53 kg., immediately brought into a flask and subjected to distillation in a current of steam. The first small portions of distillate were separately collected. These liquids were perfectly neutral and gave no reaction for hydrogen cyanide by the usual tests. They possessed the characteristic, peach-like odor, but not that

<sup>1</sup> Windisch, *Z. Nahr. Genussm.*, **4**, 819 (1901).

of benzaldehyde, which would doubtless also have been present if hydrogen cyanide were produced from this fruit. The absence of the latter compound was furthermore confirmed by an examination of the first portions of distillate from a very large quantity of peach pulp.

For a complete investigation of the odorous constituents of the fruit, distillations were conducted with separate large portions. The peaches were ripe, in the freshest possible condition, and consisted entirely of the choice variety known as the "Georgia Belle."

### First Distillation.

In order to obtain some information respecting the general characters of the total odorous constituents, a quantity (106.6 kg.) of the fresh peach pulp was distilled in one operation, and without any added water, in a current of steam. The amount of distillate collected was about 65 liters. This liquid was repeatedly cohobated in a current of steam until the odorous substances were finally concentrated in a volume of 4 liters. The large quantity of practically odorless aqueous liquid remaining from this treatment was made alkaline with sodium hydroxide and evaporated, in order to obtain the volatile acids, as will subsequently be described.

The concentrated distillate was practically neutral to litmus, had an exceedingly fragrant odor, and showed a slight oily film on the surface. A small portion of the liquid gave an almost immediate red coloration with sensitized Schiff's reagent, and reduced an ammoniacal solution of silver oxide, soon forming a bright, metallic mirror. With dimethylamine and sodium nitroprusside it gave the beautiful indigo-blue color which is characteristic of acetaldehyde.<sup>2</sup> A special test for formaldehyde by means of phenylhydrazine hydrochloride gave a negative result. No coloration was produced by ferric chloride, which indicated the absence of phenolic substances.<sup>3</sup>

**Test for Methyl Anthranilate.**—Although there was no evidence of the presence of methyl anthranilate, either by the odor or a fluorescence, the concentrated distillate was also examined for this compound. This was done by diluting 5 cc. of the liquid with water, and extracting three times successively with chloroform in portions of 10 cc. each. The chloroform liquids were passed through a dry filter, evaporated on a water-bath in a current of air, and the residue dissolved in 2 cc. of 10% sulfuric acid, this liquid being then treated with sodium nitrite and tested with

<sup>2</sup> THIS JOURNAL, 42, 1511 (1920).

<sup>3</sup> Traphagen and Burke, *ibid.*, 25, 242 (1903), state that they found very small amounts of salicylic acid in a great variety of fruits and vegetables, including apples and peaches. We are unable to confirm their observations with respect to either of the last mentioned fruits.

$\beta$ -naphthol in the manner which has previously been fully described.<sup>4</sup> A completely negative result was obtained.

### Extraction and Characteristics of the Essential Oil.

The entire amount of concentrated aqueous distillate was subsequently extracted five times successively with pure, aldehyde-free ether, the united ethereal liquids were dried with anhydrous sodium sulfate, and the greater part of the solvent was removed by distillation. The residual liquid was then divided into two exactly equal portions, one of which was reserved, while the other was brought into a small tared flask, and the ether allowed to evaporate spontaneously. A small amount of a pale yellow, limpid oil was thus obtained, which possessed an exceedingly fragrant and intense peach-like odor. When cooled somewhat below the ordinary temperature, it formed a concrete, transparent mass, which was interspersed with small acicular crystals, the latter evidently consisting of a paraffin hydrocarbon, as will subsequently be shown. The amount of essential oil thus obtained was 0.3940 g., and as this represented one-half of the original ethereal solution, the total yield of oil was 0.7880 g., or 0.00074 % of the peach pulp employed. In another operation in which 155.6 kg. of pulp of "Georgia Belle" peaches was distilled, and the entire distillate extracted with ether, 1.2774 g. of essential oil was obtained, corresponding to a yield of 0.00082 %.

A trace of the oil, when shaken with a little water, gave all the previously mentioned reactions for an aldehyde, including that characteristic of acetaldehyde. With aniline and a drop of dil. hydrochloric acid it gave the intense red color characteristic of furfural, this compound having doubtless been produced during distillation by the action of the organic acids on the sugar of the fruit. A little of the oil was dissolved in glacial acetic acid and a drop of conc. sulfuric acid added, when a purplish-red color soon developed, similar to that produced by cadinene.<sup>5</sup>

The essential oil from peaches is an exceedingly unstable product. When kept for a few weeks in a narrow glass tube with a capillary constriction, and only occasionally exposed to the air, it became converted into a black, viscid mass, and had then completely lost its original fragrance. It is therefore necessary for its preservation to bring it immediately after extraction from the distillate into a glass tube, which should be hermetically sealed, and when thus protected it appears to remain unchanged.

Inasmuch as one of the above-mentioned color reactions of the oil had indicated the presence of cadinene, it was at first thought that its instability was due entirely to this compound, but the subsequent in-

<sup>4</sup> THIS JOURNAL, 43, 380 (1921).

<sup>5</sup> It may be noted that a somewhat concentrated solution of furfural in glacial acetic acid also gives a coloration with sulfuric acid, but with so small an amount of furfural as that employed for the test with peach oil no perceptible color is produced.

vestigation of the odorous constituents has shown that these are also readily decomposed. It was, nevertheless, thought possible that some further evidence of the presence of cadinene might be obtained, and the remaining half of the above-mentioned ethereal solution, containing 0.3940 g. of the oil, was employed for this purpose. The solution was first saturated with dry hydrogen chloride, and after keeping for several days the ether was allowed to evaporate completely. A small amount of a dark colored product was thus obtained, which was treated with a little alcohol, when some crystalline flakes separated. These were collected and dried on a porous tile. After purification, the substance formed pearly laminae, melting at about  $52^{\circ}$ , and evidently consisted of a paraffin hydrocarbon, since conc. nitric and sulfuric acids had no action upon it. The alcoholic filtrate from the original crystalline substance was evaporated, and the residue treated with ethyl acetate. On allowing the latter solution to evaporate spontaneously, a few fine, colorless needles separated, but the amount of this substance was much too small to permit of its identification. Although no direct evidence of the presence of cadinene in the oil could thus be obtained, it is possible that this was due to the exceedingly small amount of material available for the experiment.

The previously mentioned 4 liters of concentrated distillate, which had been extracted with ether for the purpose of obtaining the essential oil, was subsequently made alkaline with sodium hydroxide and evaporated. The liquid was then acidified with sulfuric acid and distilled in a current of steam, about 1 liter of distillate being collected. This liquid was very faintly acid, and, after treatment with baryta for the purpose of obtaining a barium salt, was found to contain formic acid. The latter was removed by means of potassium permanganate, and the presence of a small amount of acetic acid was then determined by the usual tests. The concentrated distillate, after the extraction of the essential oil, therefore appeared to contain only small amounts of formic and acetic acids.

### Second Distillation.

The product of this distillation was specially designated for an examination of the esters contained in the fruit. The amount of peach pulp employed was 108.4 kg., and about 65 liters of distillate was collected.

### Hydrolysis of the Esters. Evidence of the Presence of Linalool.

The entire original distillate was concentrated by repeated cohobation in a current of steam until the odorous constituents were contained in a volume of about 2 liters. The large quantity of practically odorless aqueous liquid remaining from this treatment was made alkaline with sodium hydroxide, evaporated, and then reserved for the examination of the volatile acids. The concentrated distillate was brought into a

flask provided with a reflex condenser, 25 g. of pure sodium hydroxide added, and the whole kept in a state of active ebullition for one hour. It had then acquired a deep yellow color, and separated a small amount of aldehyde resin. After cooling, the liquid was distilled in a current of steam, the receiver being cooled with ice, and about 800 cc. of distillate was collected. The first portions which passed over were milky, and some oily drops soon separated. This entire distillate, which had a delightful fragrance reminding of linalool, was extracted 5 times successively with pure aldehyde-free ether, and the united ethereal liquids dried with anhydrous sodium sulfate. They then gave no reaction for aldehyde with sensitized Schiff's reagent. The alkaline liquid remaining from the operation of hydrolysis was reserved for the examination of the volatile acids, as subsequently described.

The distillate which had been extracted with ether was saturated with sodium chloride in order to examine it for methyl alcohol. After extraction with light petroleum, it was distilled in a current of steam, about 500 cc. of distillate being collected. This was subjected to 7 successive distillations until the more volatile constituents were finally contained in 2 cc. of liquid, the last two distillates being cooled with ice. A very small portion (0.1 cc.) of this liquid, when oxidized with potassium permanganate in strongly acid solution, developed the odor of formaldehyde, and when further treated according to the method of Denigès, as elaborated by von Fellenberg,<sup>6</sup> a decided reaction for this aldehyde was obtained, a deep bluish-violet color with Schiff's reagent being soon produced. This result established the presence of an exceedingly small amount of methyl alcohol, which may have been formed during the original process of distillation by the hydrolysis of a methyl ester of pectin.<sup>7</sup>

The above-mentioned ethereal extract of the distillate obtained after hydrolysis was distilled in order to remove the greater portion of the ether, and the concentrated residual liquid, which had the odor of linalool, brought into a small pressure flask, in which it was allowed to evaporate spontaneously, the last portion of ether being withdrawn by suction. The yellowish, oily residue had a fragrant odor and contained a small amount of solid substance, which probably consisted of a hydrocarbon. The weight of this residue was 0.2620 g., thus representing 0.00024% of the weight of peach pulp employed, or about one-third as much as the yield of essential oil.

Having ascertained by a preliminary experiment that so small a quantity of linalool as 0.1 g. was capable of yielding on oxidation an amount of citral that could readily be recognized by its odor and some special tests,

<sup>6</sup> Denigès, *Compt. rend.*, 150, 529 (1910); and von Fellenberg, *Biochem. Z.*, 85, 45 (1918).

<sup>7</sup> *THIS JOURNAL*, 42, 1517 (1920).

the above-mentioned oily residue was treated as follows. To the product of hydrolysis, contained in a small pressure flask, there was gradually added, while being kept cool, 5 cc. of a chromic acid mixture,<sup>8</sup> when a transient bluish coloration was first produced. The flask was then closed, and heated on a water-bath, with occasional agitation, at a temperature of about 90° for 15 minutes. The mixture was then cooled, diluted with water, and extracted with 3 successive portions of pure, aldehyde-free ether. The united ethereal liquids, after being washed with a little water, were dried with anhydrous sodium sulfate, and then filtered into a small distilling flask, in which the ether was allowed to evaporate spontaneously. Any ether vapor remaining in the flask was removed by aspiration. The residual product, which had the pronounced odor of citral, was a yellowish oil containing a small amount of solid substance, the latter probably consisting of a paraffin hydrocarbon. A small amount of water was added, and the mixture distilled in a current of steam, about 5 cc. of distillate being first separately collected. This was perfectly neutral to test-paper, contained some oily drops, and had a fragrant, lemon-like odor. A small portion of the liquid on the addition of sensitized Schiff's reagent soon developed a purplish color. It rapidly reduced an ammoniacal solution of silver oxide, and on keeping for some time a bright metallic mirror was formed. The oxidation product thus obtained evidently consisted of citral, but the amount was much too small to permit of the preparation of a derivative. As the hydrolytic product from which it was produced had the pronounced, characteristic odor of linalool, it may safely be concluded that this represents the chief alcoholic constituent of the peach distillate, and that it is present in the form of esters.

#### Acids Obtained by the Hydrolysis of the Esters.

The alkaline liquid remaining after the distillation of the linalool from the previously described operation of hydrolysis was united with a similar liquid obtained by the hydrolysis of a distillate from 14.18 kg. of peach pulp, which will subsequently be noted, and the whole filtered in order to separate a small amount of aldehyde resin. The liquid was then acidified with sulfuric acid and distilled in a current of steam, about 1.5 liters of distillate being collected. The first portion of the distillate was strongly acid, cloudy, and separated a slight oily film on the surface. The entire liquid, which had an odor resembling that of the higher fatty acids, was made alkaline with baryta, concentrated, and the excess of baryta removed by carbon dioxide. The filtered liquid rapidly reduced mercuric chloride and silver nitrate, and evidently contained a considerable amount of formic acid. This was removed by treatment with a 4% solution of potassium permanganate, a current of carbon dioxide being meanwhile

<sup>8</sup> *J. prakt. Chem.*, **45**, 599 (1892).

passed through the liquid. The filtered, neutral solution of barium salts then gave with silver nitrate a small amount of a precipitate, which was collected and analyzed.

Fraction I. Subs., 0.0377: Ag, 0.0164. Calc. for Ag,  $C_8H_{15}O_2$ : Ag, 43.0. Found: 43.5.

This result indicated the presence of caprylic acid, of which further conclusive evidence was subsequently obtained.

The filtrate from the preceding salt gave no further precipitate by the direct addition of silver nitrate, but after concentration it yielded the following additional portions of silver salt.

Fraction II. Subs., 0.0188: Ag, 0.0105. Found: 55.8.

Fraction III. Subs., 0.0502: Ag, 0.0306. Found: 60.9.

Although Fraction II agrees well with silver butyrate, which requires Ag = 55.4%, this is regarded merely as a coincidence, since this fraction as well as Fraction III, when moistened with dil. sulfuric acid, developed the unmistakable odor of valeric acid. The two fractions undoubtedly consisted of mixtures of silver valerate and acetate, these salts requiring respectively Ag = 51.7 and Ag = 64.6%. The total amount of silver salt from the acids obtained by hydrolysis was 0.1653 g. On evaporating the final mother-liquor from these salts, and heating the residue with a little alcohol and strong sulfuric acid, the characteristic odor of ethyl acetate was developed. It may thus be considered that by the hydrolysis of the esters, formic, acetic, valeric and caprylic acids are produced.

### Third Distillation.

It was observed in connection with some preliminary tests of the peach distillate that an appreciable amount of acetaldehyde was present. In order to confirm the identity of this substance and also to ascertain whether any other aldehydic, or possibly ketonic, compound was contained in the fruit, the entire product of one distillation was employed chiefly for this purpose. A considerable quantity (120.2 kg.) of peach pulp was accordingly distilled with steam, and about 65 liters of distillate collected. This liquid was concentrated by repeated cohobation in a current of steam until the odorous constituents were eventually contained in a volume of 2 liters. The large quantity of practically odorless liquid remaining from this operation was made alkaline with sodium hydroxide and evaporated, in order to obtain the volatile acids, as in the case of the previous distillations.

### Identification of Acetaldehyde.

The above-mentioned 2 liters of concentrated distillate was saturated with sodium hydrogen sulfite, and this solution was unavoidably kept for a period of 6 weeks before further treatment. It was then extracted

thrice successively with pure aldehyde-free ether in order to remove the uncombined substances, the united ethereal liquids being washed with small portions of water, dried with anhydrous sodium sulfate, and reserved for further examination. After passing a current of air through the acid sulfite solution to remove any dissolved ether, sufficient sodium carbonate was added to render it distinctly alkaline, and the mixture distilled in steam, about one liter of total distillate being collected. The first portion of the distillate was opalescent, and separated a slight oily film on the surface. It possessed a pleasant odor, resembling that of the higher aliphatic aldehydes, and it also gave all of the previously described reactions of this class of compounds, including that characteristic of acetaldehyde.

The above mentioned distillate containing the aldehyde was treated with an alkaline solution of potassium permanganate until after keeping for some time the red color remained permanent. After separating the manganese dioxide, the excess of permanganate was removed by the addition of a solution of ferrous sulfate in dil. sulfuric acid, and the acid liquid distilled in a current of steam. About 3 liters of distillate was collected, the first portions of which had a strongly acid reaction and showed a distinct opalescence, but the entire distillate was practically odorless. The acid was converted into a barium salt, from which several fractions of silver salt were obtained and analyzed.

Fraction.	Subs. G.	Ag. found. G.	%.
I	0.0302	0.0189	62.6
II	0.0659	0.0423	64.2
III	0.0396	0.0254	64.2
IV	0.0255	0.0164	64.3
V	0.2158	0.1388	64.3
VI	0.0863	0.0555	64.3
VII	0.0870	0.0559	64.3

Calc. for  $\text{AgC}_2\text{H}_3\text{O}_2$  : Ag, 64.6.

It is evident from these results that the aldehydic constituent of peaches consists almost entirely of acetaldehyde, with a very small amount of a higher homolog.

The total amount of silver salt obtained in the above operation was 0.8330 g., which would correspond to 0.2189 g. of acetaldehyde, or 0.00018% of the weight of pulp employed. Inasmuch as the yield of essential oil, which would contain but little of the aldehyde, was 0.00074%, the proportion of the latter compound in the peach distillate was relatively large. It is a rather remarkable coincidence that the proportion of aldehyde to essential oil is practically the same in peach pulp as that found in the rind or parings of the apple, being in the former about 1:4.1 and in the

latter 1:4.3, but the percentage amounts of both constituents are very much larger in the apple parings.<sup>9</sup>

**Hydrolysis of the Essential Oil Extracted from the Acid Sodium Sulfite Solution.**—As the previously mentioned ethereal extract of the acid sulfite solution might be considered to contain the constituents of the essential oil, with the exception of the aldehyde, it was carefully examined. The greater part of the ether was first removed by distillation, and the residual liquid brought into a small flask in which the ether was allowed to evaporate completely. There then remained a few drops of a yellowish oil, together with some crystalline substance, which probably consisted of a paraffin hydrocarbon. To this oily material a solution of 5 g. of pure sodium hydroxide in 100 cc. of water was added, and the whole heated under a reflux condenser for one hour, after which it was distilled in steam. The distillate, which had a pleasant, but somewhat terpene-like odor, separated a few oily drops. It was extracted thrice with pure, aldehyde-free ether, the ethereal liquid dried with anhydrous sodium sulfate and, after removing the greater part of the solvent by distillation, the last portion was allowed to evaporate in a small pressure flask. To the very slight residue thus obtained, there was added a small quantity of a chromic acid mixture,<sup>8</sup> and the whole heated on a water-bath at a temperature of about 90° for 15 minutes. After cooling, water was added, and the liquid extracted thrice with aldehyde-free ether, the ethereal liquids being then washed with a little water, dried with anhydrous sodium sulfate, and allowed to evaporate in a flask adapted for steam distillation. The scarcely perceptible residue, when mixed with water and distilled, yielded a perfectly neutral distillate, which possessed no odor, and even the first small portion of distillate, which had been cooled with ice, gave no reaction with Schiff's reagent.

Having previously ascertained that the odorous constituents of the peach consist chiefly of the esters of linalool, which must therefore be contained in the essential oil, and it being known that linalool on gentle oxidation with chromic acid yields citral, it can only be concluded that by the above-described treatment with acid sodium sulfite the linalool had become completely decomposed. In order to confirm this supposition 5 g. of linalool was added to 100 cc. of a saturated solution of acid sodium sulfite and the mixture allowed to stand, with occasional agitation, for 5 weeks. It was then extracted with ether, the ethereal liquid washed with water, dried with anhydrous sodium sulfate, and the solvent removed. The

<sup>9</sup> Müller and Osterwelder, *Landw. Jahrb. Schweiz.*, 29, 400, 509 (1915), have noted the occurrence of acetaldehyde in the juice of pears, especially that from over-ripe or soft fruit, and state that it is seldom produced in the apple, which is not in accordance with our observations. Compare THIS JOURNAL, 42, 1522 (1920). The same authors remark that this compound is not present at all, or at most in minute amounts, in sound grapes and, furthermore, that it does not occur in fruits until they are completely ripe.

small amount of substance thus obtained distilled almost completely between 160 and 170° as a colorless liquid which had the odor of terpenes and of which it appeared to consist. On keeping for some time it formed a transparent, jelly-like mass.

**Acids Obtained by the Hydrolysis of the Essential Oil.**—The alkaline liquid remaining from the hydrolysis of the product extracted from the acid sulfite solution, as above described, was acidified with sulfuric acid and distilled in steam. The distillate, which was somewhat opalescent, had a distinctly acid reaction, and an odor reminding of valeric acid. It was made alkaline with baryta, concentrated, and the excess of baryta removed by carbon dioxide. The filtered, neutral solution of barium salt was found to contain some formic acid, and this was therefore removed by treatment with potassium permanganate, the liquid being then filtered and concentrated. On the subsequent addition of silver nitrate a small amount of a purely white silver salt was precipitated, which on analysis gave the following result.

Subs. 0.0211: Ag, 0.0089. Calc. for  $\text{AgC}_8\text{H}_{15}\text{O}_2$ : Ag, 43.0. Found: 42.2.

This result indicated the presence of caprylic acid, and the salt developed a fatty odor on ignition.

As the filtrate from the above-mentioned salt gave no further precipitate on the addition of silver nitrate, it was concentrated, when an additional small amount of silver salt was obtained. This was collected and analyzed.

Subs. 0.0249 : Ag, 0.0148. Found: Ag, 59.4.

The composition and characters of this fraction of salt indicated that it consisted of a mixture of silver valerate and acetate in nearly equal proportions. It may thus be concluded that by the hydrolysis of the small portion of original oily material formic, acetic, valeric, and caprylic acids were produced.

#### Emanation of Acetaldehyde from Ripe Peaches.

Having ascertained, as already noted, that the distillate from peaches contained an appreciable amount of acetaldehyde, it was deemed of interest to determine whether, as in the case of apples,<sup>10</sup> this substance could be detected in the exhalations from the fruit. This operation was conducted by aspirating dry air through a large glass percolator containing a quantity of sound, free-stone peaches. As it was desirable that the fruit should not become over-ripe on keeping, it was in the beginning somewhat hard, and was carefully packed in sections, in order to avoid injury by pressure. The percolator was provided at the bottom with an exit tube which was first connected with a bulb apparatus containing a saturated solution of sodium hydrogen sulfite. To this apparatus a empty gas-washing bottle was attached, and to the latter a similar bottle

<sup>10</sup> THIS JOURNAL, 42, 1523 (1920).

containing some of the acid sulfite solution, the whole being connected through an intervening empty flask with a filter pump, by means of which the air was drawn continuously for 3 days through the entire system. The number of peaches used for this experiment was 260, and their total weight was 15.66 kg. During the operation the peaches had become artificially ripened, and the absorbing apparatus was then detached. The acid sulfite solution, which amounted altogether to 300 cc., was found to possess no fruity odor, as was the case in the previously noted experiment with apples.<sup>10</sup> The liquid was made alkaline with sodium carbonate and distilled, 50 cc. of distillate being first collected, and this was then concentrated by re-distillation to a volume of 5 cc., the receiver having been cooled with ice. A small portion of this liquid, when tested with sensitized Schiff's reagent, gave an almost immediate pink coloration, and with an ammoniacal solution of silver oxide a reduction of the silver soon ensued. It could thus be concluded that a very small amount of acetaldehyde was contained in the emanation of the peach, although not sufficient to afford the specific reaction with dimethylamine and sodium nitroprusside. Since the texture of the outer surface of this fruit is very different from that of the apple, it was naturally to be expected that the exhalation of aldehyde would be relatively small.

**Distillation of the Peach Pulp and Identification of Methyl Alcohol.**—The fruit which had been used for the above-described experiment was carefully deprived of the pits, and the pulp then amounted to 14.18 kg. This was distilled in a current of steam, and about 12 liters of distillate collected. The first portion of the distillate was specially tested for hydrogen cyanide, but with a wholly negative result. The entire distillate was then repeatedly cohobated in a current of steam until the odorous constituents were finally contained in a volume of 0.5 liter, the remaining aqueous liquids, which were practically odorless, being then made alkaline with sodium hydroxide and added to the similar liquids from previous operations for the recovery of volatile acids.

To the above-mentioned concentrated liquid 10 g. of sodium hydroxide was added, and the mixture, contained in a flask provided with a reflux condenser, was kept in a state of active ebullition for one hour. It had then acquired a deep yellow color, due to the presence of aldehyde, and was subsequently distilled, about 300 cc. of distillate being collected. The alkaline liquid remaining in the distillation flask was eventually added to the larger quantity of similar product obtained in a previously described operation. After saturating the distillate with sodium chloride, it was extracted thrice successively with light petroleum ether (b. p. 30 to 55°) in order to remove any higher alcohol or other neutral compound, and the petroleum liquids were reserved for further examination. The aqueous salt

solution was then distilled, about 100 cc. of distillate being first collected, and this was then concentrated by further repeated distillations until the more volatile substances were contained in a volume of 2 cc., the receiver in the later distillations having been cooled with ice. A very small portion (0.1 cc.) of the final distillate, when oxidized with potassium permanganate in strongly acid solution, developed a pronounced odor of formaldehyde, and when further tested with Schiff's reagent in the previously described manner, it gave within 15 minutes a deep bluish-violet color. This result established the presence of a small amount of methyl alcohol, and confirmed the previously noted observation respecting its occurrence. On examining the remainder of the concentrated liquid for ethyl alcohol by means of the iodoform test a wholly negative result was obtained.

**Examination of the Petroleum Extract of the Hydrolyzed Product.**—The above-mentioned petroleum extract of the hydrolyzed product was distilled in order to remove the greater part of the solvent, and the residual liquid allowed to evaporate in a small pressure flask, the last traces of petroleum being then removed by aspiration. A minute quantity of a yellowish oil was thus obtained, and to this was added 1 cc. of a chromic acid mixture.<sup>8</sup> After closing the flask, the mixture was heated for 15 minutes on a water-bath, then cooled, diluted with water, and extracted with 3 successive portions of aldehyde-free ether. The ethereal liquids were washed with a little water, dried with anhydrous sodium sulfate, and allowed to evaporate in a small distilling flask, the last portion of ether vapor being withdrawn by suction. The very slight residue had a distinct odor of citral. It was mixed with a small amount of water, and the whole distilled in a current of steam, about 2 cc. of distillate being first collected. This liquid was neutral, gave a faint pinkish coloration with Schiff's reagent, and quickly reduced an ammoniacal solution of silver oxide, thus indicating that a small amount of linalool was contained in the hydrolyzed product.

**Examination of the Aqueous Liquids Remaining from the Cohobation of the Original Peach Distillates. Evidence of the Presence of Formic, Acetic, Valeric and Caprylic Acids.**

The aqueous liquids from which the odorous constituents had been removed as completely as possible by repeated cohobation in a current of steam were all united, made alkaline with sodium hydroxide, and concentrated. The liquid was then filtered, acidified with sulfuric acid, and distilled in steam until the distillate no longer had a distinctly acid reaction. About 2.5 liters of liquid was thus collected. The first portion of the distillate, which was strongly acid, was cloudy and separated some

yellowish oily drops. It had an odor which was not particularly agreeable, resembling that of the higher fatty acids.

As only the first 0.5 liter of distillate contained some oily drops an attempt was made to separate these mechanically, and this was accomplished by means of a small separatory funnel. The acid was then converted into a barium salt, and this was first treated with a few drops of a dilute solution of potassium permanganate in order to remove traces of a reducing substance. After filtering and concentrating the liquid it gave with silver nitrate a small amount of a white, curdy precipitate, which was collected and analyzed.

Subs. 0.0264: Ag, 0.0113. Calc. for  $\text{AgC}_8\text{H}_{15}\text{O}_2$ : Ag, 43.0. Found: 42.8.

The oily drops thus consisted of practically pure caprylic acid.

After the separation of the small amount of oily acid the entire distillate was made alkaline with baryta, concentrated, filtered, and the excess of baryta removed by carbon dioxide. It was then found that the neutral liquid rapidly reduced mercuric chloride and silver nitrate, which indicated the presence of a considerable proportion of formic acid. This was accordingly removed by treatment with a 4% solution of potassium permanganate in a current of carbon dioxide, and the liquid again filtered and concentrated. On the subsequent addition of silver nitrate two successive fractions of silver salt were obtained, which gave the following results on analysis.

Fraction I. Subs. 0.0570: Ag, 0.0247. Fraction II. Subs. 0.0602: Ag, 0.0259. Calc. for  $\text{AgC}_8\text{H}_{15}\text{O}_2$ : Ag, 43.0. Found: I, 43.3; II, 43.0.

These results afforded further confirmation of the presence of caprylic acid.

The filtrate from the preceding fractions yielded a series of silver salts, which were collected and analyzed.

Fraction.	Subs. G.	G.	Ag found. %
III	0.0383	0.0184	48.0
IV	0.0367	0.0196	53.4
V	0.0869	0.0510	58.7
VI	0.0631	0.0372	58.9
VII	0.0427	0.0266	62.3
VIII	0.0520	0.0366	64.6
IX	0.0718	0.0465	64.7
X	0.0384	0.0208	64.6

Calc. for  $\text{AgC}_8\text{H}_9\text{O}_2$ : Ag, 51.7. Calc. for  $\text{AgC}_2\text{H}_3\text{O}_2$ : Ag, 64.6.

In considering the composition of the above-mentioned series of salts, it may be noted that when very small amounts of most of them were moistened with dil. sulfuric acid they developed the strong and unmistakable odor of valeric acid. It may therefore be concluded that Fraction III consisted of a mixture of silver valerate and caprylate in about equal proportions, and the Fractions IV to VII inclusive, mixtures of silver

valerate and acetate, while the subsequent fractions, as is evident from the figures, represented practically pure silver acetate. The aqueous liquid obtained by the repeated cohobation of the original peach distillate must therefore have contained formic, acetic, valeric and caprylic acids. The total amount of silver salt obtained from the aqueous liquid, of which the fractions analyzed formed a part, was 1.5402 g

### Summary.

The results of the present investigation, for which only the pulp of choice, ripe peaches was employed, may be summarized as follows.

1. The odorous constituents of the fruit may be considered to consist chiefly of the linalyl esters of formic, acetic, valeric, and caprylic acids, together with a considerable proportion of acetaldehyde and a very small amount of an aldehyde of higher molecular weight. It is probable that the volatile acids are present to some extent in a free state.

2. A minute amount of acetaldehyde is contained in the emanation from the entire ripe fruit.

3. No trace of hydrocyanic acid or benzaldehyde could be detected in the distillate from peach pulp. It may therefore be concluded that the occurrence of the glucoside amygdalin is restricted to the kernels of the fruit, and that no compound capable of yielding hydrocyanic acid is present in the pulp.

4. By extracting a concentrated distillate of the peach with ether a very small quantity of an essential oil was obtained. This was a pale yellow, limpid liquid, which possessed an exceedingly fragrant and intense peach-like odor. When cooled somewhat below the ordinary temperature, it formed a concrete, transparent mass, which was interspersed with minute, acicular crystals. These crystals evidently consisted of a paraffin hydrocarbon, which, when indirectly isolated, were found to melt at about 52°. The yield of essential oil was 0.00074% of the weight of pulp employed.

In addition to the above-mentioned esters, the peach oil was found to contain a little acetaldehyde and furfural, the latter having doubtless been produced during the process of distillation by the action of the organic acids on the sugar contained in the fruit. The presence of cadinene, or a compound giving a similar color reaction, was also indicated.

The essential oil of peach is an exceedingly unstable product. When kept for a comparatively short time in a glass tube with a capillary constriction, and only occasionally exposed to the air, it became converted into a black, viscid mass, and had then completely lost its original fragrance. This change is in accordance with the character of the constituents of the oil as determined by the present investigation. If the oil, as first obtained,

be brought into a glass tube, and hermetically sealed, it appears to be capable of preservation for an indefinite period.

Although a product based upon the results of this investigation may be made synthetically which represents to a considerable degree the fragrance of the peach, the exact reproduction of the natural aroma of the fruit presents an apparently insurmountable difficulty. This is largely due to the fact that in the preparation of its esters linalool undergoes intramolecular changes with the formation of the isomeric compounds geraniol and terpineol or their respective esters, and as these esters have similar boiling points no means are available for their separation. It is also well known that in the esterification of linalool dehydration of the alcohol occurs to some extent, with the formation of terpenes, which are difficult to eliminate completely from the product. This is particularly the case in the preparation of linalyl formate, even when the usual precautions are observed and the ester is distilled in a vacuum. Furthermore, the linalyl esters, when obtained in the purest possible state, are subject to somewhat rapid decomposition on exposure to the air.

WASHINGTON, D. C.

### NOTES.

**Azo Compounds from Diketo-hydrindene.**<sup>1</sup>—It is generally known that substances containing a hydrogen atom replaceable by a metal when treated with diazo chlorides give the corresponding azo compounds. This fact suggested to us that 1,3-diketo-hydrindene which has a  $>\text{CH}_2$  group situated between two "CO" groups would react with diazo chlorides in a similar way, giving azo compounds. We prepared a few azo compounds with *p*-nitro-aniline, benzidine, *p*-toluidine and  $\beta$ -naphthylamine, and diketohydrindene, in the hope that they might be found to be useful as dye stuffs. They all give very insoluble sodium salts, and the colors are very fast. We dyed several pieces of linen with them indirectly; but whether they will be of any commercial interest remains to be seen.

Diketo-hydrindene changes very readily to anhydro-*bis*-diketo-hydrindene. In the case of benzidine we have actually isolated a condensation product of *bis*-diketo-hydrindene and the corresponding diazo compound by bringing about the coupling of the constituents at ordinary temperature instead of in a freezing mixture.

<sup>1</sup> Read before the All-India Science Congress, 1920.

*p*-nitro-aniline was diazotized with suitable precautions and 1.5 g. of diketo-hydrindene dissolved in excess of sodium hydroxide solution was gradually added to it. The temperature was not allowed to rise above 5°. A solid of yellow color separated. This was allowed to stand for 2 hours, was acidified with dil. sulfuric acid, filtered and then thoroughly washed free from acid. This was dried and recrystallized from pyridine. The compound does not melt even at 280°. It dissolves in conc. sulfuric acid with a red color. In potassium hydroxide it dissolves to form a magenta colored solution.

*Analyses.* Subs., 0.1347: CO<sub>2</sub>, 0.3010; H<sub>2</sub>O, 0.0401. Subs., 0.1718: N<sub>2</sub>, 21.6 cc. (24°, 754 mm.).

Calc. for C<sub>15</sub>H<sub>9</sub>O<sub>4</sub>N<sub>3</sub>: C, 61.0; H, 3.0; N, 14.2. Found: C, 60.9; H, 3.2; N, 13.9.

**Benzidine-azo-diketo-hydrindene.**

1.84 g. of benzidine was tetrazotized and to this 3 g. of diketo-hydrindene, dissolved in excess of sodium hydroxide solution was gradually added, the temperature being kept below 5°. This was allowed to stand for some time and then acidified. The dark red precipitate that separated was filtered and washed repeatedly. The compound was insoluble in almost all the solvents, such as alcohols, ether, chloroform acetone, xylene and pyridine. With conc. sulfuric acid it gives a violet colored solution.

*Analysis.* Subs., 0.1649: N<sub>2</sub>, 17.5 cc. (32°, 756 mm.).

Calc. for C<sub>30</sub>H<sub>18</sub>O<sub>8</sub>N<sub>4</sub>: N, 11.3. Found: 11.3.

1.84 g. of benzidine was tetrazotized as usual and to this an equivalent quantity of alkaline solution of diketo-hydrindene was added. The solution was kept overnight at ordinary temperature (about 26°), then acidified, filtered and washed.

*Analysis.* Subs., 0.2294: N<sub>2</sub>, 14.9 cc. (28°, 766 mm.).

Calc. for C<sub>48</sub>H<sub>26</sub>O<sub>8</sub>N<sub>4</sub>: N, 7.6. Found: 7.5.

***p*-Toluidine-azo-diketo-hydrindene.**

— One g. of

*p*-toluidine was diazotized in the usual way and coupled with 1.5 g. of diketo-hydrindene in sodium hydroxide solution at 5°. This was acidified, filtered, washed and dried. It was recrystallized from acetic acid. It separated in fine yellow silky flakes, melting at 211°. It dissolves in conc. sulfuric acid to form a chocolate colored solution.

*Analysis.* Subs., 0.1743; N<sub>2</sub>, 16 cc. (23°, 756 mm.).

Calc. for C<sub>16</sub>H<sub>13</sub>O<sub>2</sub>N<sub>2</sub>: N, 10.6. Found: 10.3.

$\beta$ -naphthylamine-azo-diketo-hydrindine.

1.43 g. of  $\beta$ -naphthylamine was diazotized and coupled with 1.5 g. of diketo-hydrindene in alkali solution at 5°. This was acidified, filtered, washed and dried. It was recrystallized from acetic acid. It melts at 205°. It forms a deep brown colored solution.

*Analysis.* Subs., 0.1439. N<sub>2</sub>, 12 cc. (26°, 754 mm.).

Calc. for C<sub>19</sub>H<sub>15</sub>O<sub>2</sub>N<sub>2</sub>:N, 9.3. Found: 9.17.

**The Odorous Constituents of Apples.**—It has come to our notice that a paper has been published by Shintarô Kodama<sup>1</sup> which, as abstracted in *J. Chem. Soc.*, 120, i, 220 (1921) bears the following title: "Odorous Constituents of Apples. Esters Derived from Leucic Acid." In the original publication the title of the paper is: "On the Odor of Apples. Ethereal Oils Obtained from Leucic Acid." After stating, "Power and Chesnut have proved that amyl esters of formic, acetic, and hexoic acids are the principal odorous constituents of apples,"<sup>2</sup> Kodama proceeds to describe certain esters prepared from by-products of the decomposition of proteins, such as ethyl  $\alpha$ -acetoxy-*iso*-hexoate, and the corresponding methyl ester; ethyl  $\alpha$ -benzoyloxy-*iso*-hexoate; ethyl  $\alpha$ -isovaleryl-*iso*-hexoate, etc. Inasmuch as these compounds or "esters derived from leucic acid" do not occur in apples, and therefore do not represent their odorous constituents, the title given by Kodama to his communication is not only misleading but entirely unwarranted. It has consequently seemed desirable to call attention to these facts in order to avoid any possible confusion in the literature on the subject.

**The Occurrence of Methyl Anthranilate in Grape Juice.**—The use of fruit juices as beverages has become more extended and greatly increased in recent years, and considerable attention is now being given to the control of their quality and purity. One of the substances that has been suspected of being added to natural grape juice for the purpose of improving its flavor is methyl anthranilate, and it is well known that this compound,

<sup>1</sup> Kodama, *J. Tokyo Chem. Soc.*, 41, 965-975 (1920).

<sup>2</sup> THIS JOURNAL, 42, 1509-26 (1920).

in a dilute state, possesses a decided grape-like odor. Inasmuch as the examination of some samples of commercial grape juice, according to the method recently published by one of us,<sup>1</sup> has clearly indicated the presence of methyl anthranilate, some of those interested in these products appear to have been led to the conclusion that in such instances an artificial flavoring agent had been employed. In consequence of these deductions it has naturally become of much importance to determine whether a pure and entirely unsophisticated grape juice may not contain small amounts of methyl anthranilate. An opportunity for conducting such an investigation has been made available through the kind cooperation of Dr. J. S. Caldwell, of the Bureau of Plant Industry, U. S. Department of Agriculture, who has provided us with a large number of samples of grape juice expressed by himself during the autumn of 1920 from many different and well determined varieties of the fruit. Although the examination of all these samples has not yet been completed, the observations that have thus far been made enable us to conclude that methyl anthranilate is a natural and apparently constant constituent of grape juice. The amounts that are present in the numerous varieties of the grape appear to differ very greatly, and by far the most decisive results of the test have thus far been obtained from the red juices of the Concord type. By the distillation of 500 cc. of the grape juice the amount of methyl anthranilate found has in no case exceeded 0.001 g., as determined by comparative tests with the pure substance, but even this small amount, as has previously been shown,<sup>1</sup> is sufficient to produce a deep red color or precipitate by the interaction of the diazotized compound with  $\beta$ -naphthol. In the case of the light colored juices the amount of methyl anthranilate present, as indicated by the distillation of 500 cc. of liquid, has thus far been observed to be not more than 0.0001 g., and is frequently less, but in few instances could it be regarded as entirely absent.

It has seemed to us desirable to present these preliminary observations regarding the occurrence of methyl anthranilate in grape juice in order that those engaged in the examination or control of commercial products may not be led to wrong conclusions respecting their purity. The more complete results of the investigation of this subject must necessarily be reserved for a later communication.

## NEW BOOKS.

**James Cutbush: An American Chemist, 1788-1823.** By EDGAR F. SMITH, Provost of the University of Pennsylvania. Printed by J. B. Lippincott Co., Philadelphia, 1919. 94 pp. 10 × 14.5 cm.

As a result of his investigations of chemical development in this country Dr. Smith has given us "Chemistry in America" (1914), "Life of Robert Hare, 1781-1858" (1917), "James Woodhouse, A Pioneer in Chemistry" (1918), "Chemistry in Old Philadelphia" (1918), and now "James Cutbush," through which he has perfected the record of early chemical achievements for his native country, for the State of Pennsylvania in which he was born, for the city of Philadelphia in which he has long resided, for the University he has served so well during upwards of four decades, and for the profession in which he occupies so distinguished a position.

There is a marked contrast in the treatment of Hare in the portly volume of 508 pages, 16 by 23.5 cm. in area, with a colored portrait, and of Cutbush in this modest little pocket edition, and yet the latter appears in some ways the more fascinating, since Dr. Smith has brought to our attention a man of mystery, and also an almost mythical college.

From the record we learn that in 1808, and when but 20 years of age, Cutbush published in the Philadelphia "Medical Museum" a paper on mercury fulminate, giving the results of his endeavor to produce this body by a method in which no alcohol was employed and announcing his discovery of a mercury oxalate that was exploded by percussion. Also he published in that year a book called the "Useful Cabinet" which appears to have been a compilation of useful scientific facts and formulas. Moreover, in the "Aurora," a Philadelphia daily paper, he published in that year fifteen articles dealing with the Application of Chemistry to Arts and Manufacture which covered a wide variety of topics. While writing this review there are before me two maps showing the location in the United States of establishments of certain selected chemical industries in 1900 and in 1915 in each of which it is apparent that these industries center about Philadelphia, and history records our earliest factories in that city. One may well believe that Cutbush's active propaganda continued by public lecture courses, investigations, and publications, throughout his brief life, materially contributed toward this consummation.

In the 15 years following his first appearance in print, besides many journal articles covering his investigations, which appeared in the *American Journal of Science* and other periodicals, Cutbush published in 1812 a book on "Hydrostatics," dealing with hydrometers and their applications, in which there appeared numerous tables as well as many interesting and serviceable problems; in 1813 his "Philosophy of Experimental Chemistry" in two volumes; in 1814 the "American Artists' Manual" in two volumes, of more than 600 pages each, which was a popular dictionary of chemical

technology; in 1821 a "Synopsis of Chemistry" arranged alphabetically, comprehending the names, synonyms and definitions in that science which seems in a manner to have been a forerunner of Couch's admirable "Dictionary of Chemical Terms;" and in 1823 "Lectures on the Adulteration of Food and Culinary Poisons. . . . with a means of discovering them and rules for determining the purity of substances." This book was published at Newburgh, N. Y. and from its title Cutbush appears at that date to have entered the field so actively developed later by Wiley. In 1825, two years after his death, there was published in Philadelphia his "System of Pyrotechny" comprehending the theory and practice, with the application of chemistry, and covering 612 pages, with 44 pages of introduction.

While thus actively engaged in investigation and publication Cutbush carried on the business of "Chemist and Apothecary" at 25 S. Fourth St., Philadelphia, where, by his advertisement in 1819, it appears "complete collections of chemical reagents are kept as usual" and where "bleaching liquor, artificial musk, phosphate of mercury and other chemical preparations are prepared and sold." He gave numerous courses of public lectures and was, at the age of 23, President of the Columbian Chemical Society. He became Vice President of the Linnean Society, a founder of the Society of Philadelphia for the Promotion of National Industry, a member of the American Philosophical Society, and Professor of Chemistry, Mineralogy and Natural Philosophy in St. John's College, Philadelphia, but beyond learning that Benj. Smith Barton was professor of natural history and botany in the college, a Mr. Greiner taught there, and that the Rev. Mr. Bachman was president, Dr. Smith was not able to gather by extended search any further information as to the existence or location of this institution.

In 1814 Cutbush was appointed to the U. S. Army, with the rank of assistant apothecary-general, serving first in Philadelphia and later in the Northern division. From May 1820, he was chief medical officer of the U. S. Military Academy and Post at West Point until, on the reorganization of the Army, he became, on September 1, 1820, Post Surgeon and Acting Professor in the newly created department of Chemistry, Mineralogy and Geology, which he held until his death in 1823. Among his successors in this professorship were Dr. John Torrey, widely known as a botanist, and J. W. Bailey, an authority on the infusoria and they together with Hassler, Ellicott, Weir, and others selected by Col. Sylvanus Thayer, the "Father of the U. S. Military Academy," who were investigators and producers, as well as teachers, gave the prestige to "West Point" as an educational institution it has long continued to enjoy. Of all those who have held the professorship of chemistry, mineralogy and geology at West Point up to the present Cutbush appears to have been the only one who was primarily a chemist, though Torrey held the professor-

ships of chemistry in the College of Physicians and Surgeons, Princeton College and the College of the City of New York, and served as U. S. Assayer at New York from 1853 to 1873.

Dr. Smith designates the "System of Pyrotechny" as "the real *magnum opus* of Cutbush;" it "bears the earmarks of much careful study. It is a most worthy contribution, and is strong proof of the dominating force in the mind of Cutbush, namely, to make his science as widely useful as possible. Chemists may justly take pride in this early contribution in the application of chemical principles." He might have added that the book is "good authority" to-day and that it is doubtful whether any later book on this subject is as valuable a guide to pyrotechny or so filled with erudition.

It is obvious that the development of the rocket as an implement of warfare by Congreve was an impelling motive in the writing of this Pyrotechny for, after successful use in the bombardments of Copenhagen and Boulogne, the siege of Flushing, and the battle of Leipzig, Congreve rockets assumed an importance in the Napoleonic Wars comparable with that of the drop bomb, depth bomb, and poison gases in the Great War. The preparation and publication of this Pyrotechny was opportune and of special value to our military services, and in its preparation Cutbush wisely obeyed the principle that an application in an art is best advanced by a scientific survey of the art as a whole.

Commenting on the Aurora articles published when Cutbush was a "lad of twenty years" Dr. Smith says, "they show a wide, general knowledge and also great familiarity with the science of chemistry." The "System of Pyrotechny" is replete with learning, and besides his knowledge of chemistry and physics it evidences a wide acquaintance with foreign literature, more especially that of France yet after extended search the biographer says "Indeed, it will probably remain a query as to where he was educated."

Provost Smith has produced a delightful little book which cannot fail to entertain and enlighten all who may have the good fortune to read it.

CHARLES E. MUNROE.

•  
**La Tension de Vapeur des Mélanges de Liquides: L'Azéotropisme.** (The Vapor Pressure of Mixtures of Liquids: Azeotropism). By MAURICE LECAT. Vol. I, Experimental Results and Bibliography. Henri Lamartin, Brussels, 1918. xii + 319 pp., 200 figures. 19 X 25 cm. Price, 45 fr.

This admirable book is the first of a two-volume work devoted to a study of azeotropic liquids, that is, liquid mixtures which exhibit a maximum or a minimum boiling point.

Although the importance of this subject was evident from the researches of Roscoe in 1859-60, there has been surprisingly little advance in our knowledge regarding the prevalence of this phenomenon. In 1899,

Ryland out of 80 mixtures which he examined found no less than 45 instances of azeotropism. This led Lecat to a still wider exploration, with the result that 1050 new azeotropic mixtures were discovered.

In this volume the author first gives an introduction of 60 pages to the general theory of the vapor pressure of liquid mixtures. It is a thorough, competent, and quite the most up-to-date treatment of the subject extant. It is replete with interesting and provocative footnotes, and indicates a wide and careful study of the literature.

The second and principal part of this volume is devoted to tables of data having to do with some 2450 mixtures. In addition to the azeotropic constants, in cases where this phenomenon is shown, there are also given the density and the change of volume and of temperature on mixing. In addition boiling-point curves, total and partial vapor curves, and similar information are given whenever available. So far as possible, these data are arranged chronologically and provided with elaborate cross references to the bibliography. There are also three tables, two for binary systems showing either a maximum or a minimum vapor-pressure curve, and one for ternary systems.

These tables are followed by a list of some 1500 substances distilling at ordinary pressure and grouped under different classes such as alcohols, acids, esters, etc., arranged in order of decreasing volatility. In addition to the boiling point, the melting point, density, and critical constants are given when they are known with sufficient accuracy.

The third and last part of the volume (52 pages) contains a very excellent and valuable bibliography. In it are given first, an alphabetical list of authors with complete titles and references to their publications; second, a list of these publications (760) chronologically arranged; third, a list of the 118 periodicals or journals cited, indicating the volumes and pages where the articles appear. Each list is carefully cross referenced.

Added to the end of the book are some notes on the preparation of certain rather rare substances such as cyclohexene, isoprene, etc., in a high state of purity. There is also a rather irrelevant article by the author on the reaction of phenols, etc., with olefine hydrocarbons.

The author announces a second volume of some 400 pages devoted to a mathematical theoretical treatment of the subject.

This book merely as a compilation of our present information on this subject represents a notable achievement. If the author's experimental work proves to be as excellent as his bibliographic achievements, the completed volume will surely rank as a classic in this special field.

For this reason it is to be regretted that the author has not been able to keep certain personal grudges and animosities out of his footnotes. They certainly tend to undermine the confidence of the reader in the good judgment of the author. Perhaps they should be charitably forgotten

in consideration of the ill health which the author states he suffered, and the difficulty of doing intellectual work when his country (Belgium) was devastated by war which appeared to him as monstrous as it was insane. This situation is reflected in the dedication of the book which reads,

"To all victims of militarism, to all those, no matter to what nation they belong, who with DuBois-Reymond and Ch. Hermite condemn Chauvinism and place the interests of science above those of politics, I dedicate this work."

ARTHUR B. LAMB.

**"Ammonia and the Nitrides."** By DR. EDWARD B. MAXTED. J. and A. Churchill, London. P. Blakiston's Son and Company, Philadelphia, Pa. 114 pages, 16 illustrations, 18.5 × 12.5 cms. Price, \$2.00

This little book is an excellent summary of the information which can be gathered from the periodical literature relative to the so-called Haber Process and the reactions of free nitrogen.

In the first chapter, the author discusses the ammonia equilibrium, its calculation from the heat of formation of ammonia, and from specific-heat data. Experimental verification of this equilibrium is then presented. In the second chapter, the author describes at some length various types of pressure furnaces and the results which have been obtained with a few "classical" catalysts. The discussion of the synthesis of ammonia at very high temperatures and also by the silent discharge will prove of interest to many readers.

By far the most useful information contained in this book is found in the chapters describing the nitrides. A very fine list of references accompanies these chapters. The book closes with a chapter on active nitrogen.

Considering the great interest in nitrogen fixation this book comes at a very opportune time. However, it will disappoint anyone who expects to find in it anything new on the subject of ammonia synthesis. Had he wished, the author doubtless could have given an excellent discussion of ammonia catalysts, for example; but when we consider the jealous manner in which the different nationals have guarded their knowledge of this most important feature of the Haber Process, this omission is no doubt excusable.

ALFRED T. LARSON.

**Die störenden Einflüsse auf das Eintreten und die Eindeutigkeit analytischer Reaktionen.** By DR. W. STADLIN, Chemiker am kantonalen Laboratorium, St. Gallen. Georg Thieme, Leipzig, 1921. 70 pp. 19.5 × 13.5 cm. Price outside of Germany, M. 18.

This little book records very briefly, in catalog form, the cases in which various well-known qualitative reactions for the different inorganic and organic constituents of substance give unreliable results. Two typical

examples may be cited. Under "Aluminum," six tests are mentioned, of which the first reads as follows: "*1. Precipitation of  $Al(OH)_3$ .* Is prevented by alkali tartrates, malates, and citrates, in general by the presence of organic oxyacids and oxycompounds (sugars, starch, etc.)." Under "Benzoic Acid," three tests are given, of which the first reads: "*1. Detection by oxidation to salicylic acid. a. By means of potash.* Unreliable, because in the fusion process there is formed mainly *p*-oxybenzoic acid, which does not give the  $FeCl_3$  reaction; moreover, the small quantities of possible salicylic acid run the risk of being destroyed by the progressing process of oxidation (Stadlin, *Chem., Ztg.*, 1916, 770). *b. By means of  $H_2O_2$ .* the delicacy of the reaction is dependent on the relation of the hydrogen peroxide to the benzoic acid. Neglect of this fact may lead....." To the inorganic constituents are devoted 25 pages, and to organic substances 30 pages. In a 5-page appendix is included a similar treatment of the methods of testing blood and sperma.

A. A. NOYES.

**The Chemistry and Technology of the Diazo Compounds.** By JOHN CANNELL CAIN. Edward Arnold, London, 1920. xii + 199 pp. Price \$4.20.

This is a second edition of the well-known book which was first published in 1908. The treatment of the subject follows the same lines as in the first edition but the work has been brought up to date by the consideration of many recent investigations. A new chapter on the heterocyclic diazo compounds has been added. Altogether the book has been increased by some 30 pages. This revision of a monograph on one of the most important branches of aromatic chemistry will be welcomed by all organic chemists.

JAMES B. CONANT.

**Organic Chemical Reagents II.** By ROGER ADAMS, O. KAMM, C. S. MARVEL. University of Illinois Bulletin, Urbana, Illinois. October 11, 1920. 57 pp. 5 fig. 15 × 23 cm. Price 75 cents.

The undersigned had the opportunity a year ago<sup>1</sup> to call to the attention of his colleagues to the publication of the exceedingly useful pamphlet, "Organic Chemical Reagents," by Adams, Kamm and Marvel. The second pamphlet in the series has now appeared, describing in detail, as before, the directions for some 23 preparations which have been studied in the Chemical Laboratories of the University of Illinois. "It is desired," the authors say, "to make available to all the most satisfactory methods and reliable directions for producing various organic chemical reagents for which there is considerable demand by technical and university laboratories. A special endeavor has been made to choose wherever possible the method which may be adapted to larger scale work. Care has been

<sup>1</sup> THIS JOURNAL, 42, 1074 (1920).

taken to include all the necessary details so that there will be a minimum of difficulty in making the various substances."

The order of treatment is somewhat different from that in the first pamphlet. We have: (1) Procedure, *i. e.*, directions for the preparation of the substance; (2) Notes, giving the explanations of why it is essential to observe the conditions laid down in the directions; (3) Methods of preparation, listing the various methods in the literature, good and bad. The third caption corresponds nearer to what Beilstein calls B. (Bildung), in distinction from his D. (Darstellung). The following preparations are included in the new publication: nitroso- $\beta$ -naphthol, hydrazine sulfate, phenylhydrazine, phenyl-isocyanate, alkyl and related bromides, camphor sulfonic acid, acetonitrile, benzoyl peroxide, benzyl cyanide, phenylacetic acid, ethylphenyl acetate, fumaric and succinic acids, succinic acid, pinacone hydrate, mesitylene, *p*-nitrobenzoic acid, methyl *m*-nitrobenzoate, *m*-nitrobenzoic acid, *n*-butyl cyanide, *n*-valeric acid, ethyl *n*-valerate, *n*-amyl alcohol, and *n*-amyl amine.

Equally explicit directions and as complete a bibliography characterize Part II of the "Organic Chemical Reagents" as were found in Part I. Every user of these books, and the users will be many,<sup>2</sup> will be thankful to the authors for these two essential features.

M. GOMBERG.

**Vitamines: Essential Food Factors.** By BENJAMIN HARROW, PH. D., Associate in Physiological Chemistry, College of Physicians and Surgeons, Columbia University. E. P. Dutton and Company, 681 Fifth Avenue, New York, 1921. x + 219 pp. 8 figures. 12.5  $\times$  19.5 cm. Price \$2.50 net.

With general recognition of the importance of what may be called the Accessory Food Factors and the part which they play in the maintenance of health, this little volume may be regarded as a timely contribution.

The author has endeavored to present the most salient facts together with the best established theories in small compass and in a popular manner. The jocundly conversational style of the opening chapters will probably effect no hindrance to the fulfilment of the purpose of the book, and the later chapters present excellent summaries in a clear and terse manner. The arrangement of the material is excellent, and the description of the feed-  
desirable intr-

In the his  
to be placed  
water-solub  
the person

In his c  
which, so f  
ties of mill

All in all, however, the book offers a simple, direct, and accurate presentation of facts and theories which are of interest and of importance to the laity. It should reach a large part of the community who are desirous of being informed but who are without the background to permit or desire extended consideration of the theoretical implications.

The press work of the book is excellent.

### REPORT OF THE INTERNATIONAL COMMITTEE ON ATOMIC WEIGHTS FOR 1921-22.

A few new determinations of atomic weight have appeared since the publication of our last report. They are, briefly, as follows.

**Aluminum.**—Richards and Krepelka,<sup>1</sup> from analyses of aluminum bromide, find Al = 26.963 when Br = 79.916. This value, rounded off to 27.0, should replace the older figure.

**Bismuth.**—Hönigschmid,<sup>2</sup> from a long series of analyses of the chloride, find Bi = 209.013. Classén and Ney,<sup>3</sup> by conversion of bismuth triphenyl,  $\text{Bi}(\text{C}_6\text{H}_5)_3$  into  $\text{Bi}_2\text{O}_3$ , find Bi = 208.9967. The two values, obtained by very different methods, are in good agreement, and the value 209 may safely be adopted.

**Thulium.**—James and Stewart<sup>4</sup> have determined the ratio  $\text{TmCl}_3$  to 3Ag, which gives Tm = 169.9. This value, as obtained by a good method, should replace the figure now in use which was not supported by detailed evidence. It seems to have been only a preliminary determination which does not claim to be final.

**Nickel.**—In 1915 Baxter and Parsons published a preliminary comparison of the atomic weights of terrestrial and meteoric nickel, which

<sup>1</sup> Richards and Krepelka, *THIS JOURNAL*, 42, 2221 (1920).

<sup>2</sup> Hönigschmid, *Z. Elektrochem.*, 26, 403 (1920).

Classén and Ney, *Ber.*, 53, 2267 (1921).

<sup>4</sup> James and Stewart, *THIS JOURNAL*, 42, 2022 (1920).

was noted in the report of the committee shortly afterwards. They have now published their complete paper<sup>5</sup> and give the following values: terrestrial nickel, Ni = 58.702; meteoric nickel, Ni = 58.685. The agreement is very close, and within the range of variation ascribable to experimental errors.

## SOLUBILITIES IN MIXTURES OF TWO SOLVENTS.

BY GEORGE PUCHER AND WILLIAM M. DEHN.

Received May 29, 1920.

In a recent paper<sup>1</sup> by one of us on solubilities in mixtures of water and pyridine, it was stated<sup>2</sup> that more extensive and accurate solubility studies of pyridine, quinoline, etc. are to be made, also efforts will be made to prepare the molecular compounds indicated. This paper includes studies of solubilities both in mixtures of water and pyridine and in mixtures of alcohol and quinoline; and the molecular compound  $C_9H_7N \cdot 3CO-(NH_2)_2$ , indicated by the curve of solubilities of urea in the alcohol-quinoline mixtures, was isolated and studied.

Although constants of solubility are the most numerous and useful of chemical data, and although solutions themselves afford the media of the vast majority of chemical reactions, little is accurately known concerning either the nature of solutions or the mechanism of chemical reactions in solutions. It is true that the nature of solutions has been studied deeply from the standpoints of the phase rule, the kinetic theory, and the ionic theory, yet it can scarcely be held that the intimate nature of solvent and solute has thereby been elucidated. Cryoscopic and ebullioscopic methods have recently demonstrated the frequent existence in solution of molecular compounds aggregated of the solvent and the solute, and other physical methods have confirmed these demonstrations, but all methods failed, except rarely, to yield the molecular compound itself.

In the present and the earlier paper, the existence of the molecular compound is not only indicated by the solubility curve but the method of mixed solvents can yield the molecular compound itself. For these reasons, and because the method possesses simplicity and ease of application, it is planned to undertake other investigations with mixed solvents, the main objects of which are to study the general problem of solubility, to demonstrate that curved or broken lines of solubility indicate the formation of molecular compounds, and to separate the molecular compounds when possible.

<sup>1</sup> THIS JOURNAL, 39, 1399 (1917).

<sup>2</sup> *Ibid.*, 39, 1404 (1917).

It has been assumed that straightness of line of plotted solubilities indicates a purely physical relation of solute and solvent. This assumption is confirmed by studying the solubilities of hydrated and non-hydrated salts. The former yield curved or broken lines; the latter yield straight or nearly straight lines. Since the latter can be accounted for by a mere physical mingling of solute and water molecules, the former can be, and presumably are, accounted for by states of hydration, that is, by the formation of molecular compounds.

The existence of the most varied types of other molecular compounds in solution is set forth in the literature. These compounds have, however, only rarely been studied in connection with solubility.<sup>3</sup> The lack of study along this line may be explained by the fact that ordinary solubility is conditioned by concentration and temperature and that rising temperature decomposes the molecular compound if present. In studies of solubility in mixed solvents, however, any desired low temperature can be employed and observations and data, not possible by the former method, are obtainable.

### Experimental.

Commercial pyridine was dried with solid potassium hydroxide and metallic sodium, and distilled. The quinoline was freed from nitrobenzene and aniline and then was dehydrated by the same method. Commercial "absolute" alcohol was dehydrated by treatment with calcium carbide and then was distilled into vessels kept free from atmospheric moisture. The materials studied as solutes were taken from the usual laboratory stock and for the most part were not purified.

The determinations of solubilities, unless otherwise stated, were made at the room temperatures of 20° to 25°. The solubilities are largely expressed as grams of solute in 100 g. of the solvent. Excess of the solute and about 5 cc. of the solvent were enclosed in a small vial; the mixture was shaken vigorously or was allowed to stand until equilibrium was established. The solution was then filtered rapidly into a weighed crucible and the latter with contained solution was weighed as quickly as possible. After drying *in vacuo* or on a water-bath, the crucible was again weighed. The weight of the residue and of the solvent lost yielded the desired data. No high degree of accuracy is claimed for the solubilities given in Table I, because merely a preliminary survey of the field was made in order to find compounds behaving abnormally in the alcohol-quinoline mixture.

The first column indicates solubilities in absolute alcohol; the second, in equimolecular mixture of alcohol and quinoline; the last, in absolute quinoline. The plus sign given with the figures indicates that the solute

<sup>3</sup> The limited bibliography on solubilities of organic compounds in mixed solvents is indicated in the former paper. Ref. 1.

had partially volatilized; the  $\infty$  sign indicates that only a solid phase had formed.

TABLE I.

## SOLUBILITIES IN MIXTURES OF ALCOHOL AND QUINOLINE.

Solute.	Alcohol.	Equimolecular mixture.	Quinoline.

Xyloquinone	1.12	4.69	3.02

It will be observed in many cases that the solubilities in the mixtures of the two solvents are often either higher or lower than the solubilities in the respective pure solvents. These peculiarities are most marked in the cases of urea, saccharine, *p*-nitrophenol, acetanilide, resorcinol, piperine, cinnamic acid, and chloral hydrate. The first three gave definite

evidences of molecular-compound formation, either by the evolution of heat in mixing, or by the solidifying of the solutions at certain concentrations, or from the form of the curves obtained. Six compounds were studied in selected concentrations of mixed solvents and the data obtained are given in Tables II and III.

TABLE II.  
SOLUBILITIES IN MIXTURES OF ALCOHOL AND QUINOLINE.

%C <sub>2</sub> H <sub>5</sub> N.	Urea.	Saccharine.	Brucine.	<i>o</i> -Nitrophenol.

It will be observed that the solubilities of urea decrease quite regularly as the concentrations of quinoline increase, but at 60% a definite break occurs. At this concentration a molecular compound is formed, as shown by the following method of its preparation.

**Quinoline Tri-urea.**—To 100 cc. of absolute alcohol, sufficient urea was added to saturate at room temperature, then 110 cc. of quinoline was added while the mixture was shaken vigorously. The precipitate first formed was dissolved by gentle warming; on cooling to room temperature and standing for some hours, a white crystalline mass separated. It was filtered and washed with absolute ether. To be certain that the product contained no free urea, it was redissolved by warming in a 60% solution of quinoline in alcohol, and a little alcohol was added. The volume of the latter used was made sufficient to yield on cooling and standing only about one-half of the original precipitate. In this manner short, snow-white needles were obtained. After washing with absolute ether and drying in a desiccator, these crystals gave 31.50% of N. Calc. for C<sub>9</sub>H<sub>7</sub>N<sub>3</sub>CO(NH<sub>2</sub>)<sub>2</sub>: N, 31.70%.

Quinoline tri-urea softens at 150° and melts<sup>4</sup> at 154°. It is insoluble in ether, is easily soluble in alcohol and in hot 60% quinoline solution in alcohol. In moist air it gives off the odor of quinoline; in water it yields an oily layer of quinoline; its ready hydrolysis is indicated here. When heated above 45° ammonia<sup>4</sup> is evolved; at quite elevated temperatures, quinoline is given off. Since quinoline tri-urea and its decomposition products do not yield violet colored salts or solutions with copper sulfate, it is concluded that they do not possess a cyanuric or a biuret structure.

**Quinoline tri-urea chloroplatinate.**—This compound was formed when quinoline tri-urea, dissolved in absolute alcohol, was treated with an alcoholic solution of platinum chloride. The yellow amorphous precipitate upon recrystallization from hot water gave glistening orange needles.

<sup>4</sup> Urea melts at 132° and gives off ammonia only above 110°.

*Analyses.* Calc. for  $C_9H_7N_3CO(NH_2)_2.PtCl_4$ : Pt, 30.00; Cl, 22.01; Found: Pt, 30.07; Cl, 22.26.

This chloroplatinate is quite stable toward hot water, but with alkalis it easily yields free quinoline.

Substituted ureas, such as ethyl urea, diethyl urea, phenyl urea, did not yield by the above method molecular compounds with quinoline. Urea and pyridine also failed to yield a molecular compound.

**Saccharine in Alcohol and Quinoline.**—When the mixtures contained between 20 and 60% of quinoline, they evolved heat and solidified completely. Above 60% concentration, heat was produced and a liquid only was obtained. The indicated molecular compound of saccharine and quinoline was not isolated.

**Brucine in Alcohol and Quinoline.**—The character of this curve indicates a molecular compound. It was not isolated.

**The Nitrophenols in Alcohol and Quinoline.**—The three isomers reveal marked differences.<sup>5</sup> The *para* form gives only a solid in the equimolecular mixture of the two solvents; the *meta* form gives only a solid in pure quinoline; the *ortho* form gives a solubility curve that is nearly straight.

**Lactose in Water and Pyridine.**—The solubility curve indicates the probable formation in solution of a molecular compound.

**Raffinose in Water and Pyridine.**—A remarkable curve was obtained in these solutions and indicates the probable formation of a molecular compound. The original raffinose did not reduce copper solutions; the residues from the solutions, especially those near the 50–50% concentrations did reduce somewhat; the solutions themselves showed little or no reduction. This curve and other problems suggested by this paper will be investigated farther.

### Summary.

In mixtures of alcohol and quinoline and in mixtures of pyridine and water, certain solutes yielded solubility data indicating or demonstrating molecular compounds. Studies of solubilities in mixed solvents seem to offer a convenient method of study of additive tendencies of solute and solvent.

SEATTLE, WASH.

<sup>5</sup> It was shown by Kerryman (*Ber.* 39, 1022 (1906)) that *ortho* substituted benzene derivatives form additive compounds much less readily than the *meta* and *para* derivatives. Our data confirm this conclusion.

## A FURTHER INVESTIGATION OF THE VELOCITY OF SUGAR HYDROLYSIS.

By R. H. CLARK.

Received November 22, 1920.

The hydrolysis of cane sugar has been found by most investigators to be monomolecular with respect to sugar. If the amount of water is relatively large the velocity coefficient should be independent of the initial concentration of the sugar, according to the equation of mass action. Ostwald,<sup>1</sup> however, found that the velocity coefficient increased rapidly with the concentration of the sugar. For example, using a 0.5 *N* hydrochloric acid solution as catalyzer he found the inversion coefficient to be 20.63 for a 10% sugar solution, 22.87 for 20% and 29.16 for a 40% solution.

E. Cohen<sup>2</sup> attributed the phenomenon to the fact that the volume of the reaction is reduced the greater the concentration of the sugar and hence the number of collisions between the molecules of sugar and the hydrogen ions is increased, causing an increase in the velocity of the reaction.

That this latter view was correct was experimentally demonstrated by Rosanoff, Clark and Sibley,<sup>3</sup> by preparing three pairs of solutions, in which the acid and water had exactly the same concentration in each pair, but the sugar in one solution of each pair was replaced, in part, by glucose. Preliminary experiments were carried out to find how much glucose must be added in place of part of the cane sugar in order to keep the volumes equal. For example, in one of the pairs containing (a) 50.500 g. of cane sugar, 195.73 g. of water and 28.750 g. of formic acid in 250 cc., and (b) 14.250 g. of cane sugar, 35.00 g. of glucose, 195.73 g. of water and 28.750 g. of formic acid in 250 cc., the velocity constants of the monomolecular mass-law equation were identical, although the initial concentrations of cane sugar were in the ratio of 3.54 to 1. More recently the present writer has confirmed this result using a strong acid, hydrochloric, as catalyzer. The velocity of cane sugar hydrolysis therefore is independent of the initial concentration of the sugar when the concentrations of both acid and water are constant. Consequently the following measurements were made, to find whether in a similar manner, adding an inert substance, glucose, to keep the concentration of the water and cane sugar constant while varying the concentration of the acid, would have an appreciable effect in yielding a numerical proportionality between the quantity of hydrogen ions present and the inversion velocity.

<sup>1</sup> Ostwald, *J. prakt. Chem.*, 31, 316 (1885).

<sup>2</sup> E. Cohen, *Z. physik. Chem.*, 23, 442 (1897).

<sup>3</sup> Rosanoff, Clark and Sibley, *THIS JOURNAL*, 33, 1911 (1911).

It has long been known that there is only an approximate proportionality between the quantity of hydrogen ions and the inversion velocity of cane sugar. For example, in the case of hydrochloric acid, Ostwald found that a 0.5 *N* solution inverts 6.14 times more quickly than a 0.1 *N* solution and 64.66 times more quickly than a 0.01 *N*, although the 0.5 *N* solution contains only 4.65 times as many hydrogen ions as the 0.1 *N* and 44.73 times as many as the 0.01 *N*, as measured by the conductivity method.<sup>4</sup>

A theory to account for this variation was advanced by Arrhenius, namely, that the catalytic activity of hydrogen ions is greatly stimulated by the presence of other ions. More recently Bredig,<sup>5</sup> Acree,<sup>6</sup> Snethlage,<sup>7</sup> McBain and Coleman<sup>8</sup> and others, have advanced much evidence to show that the catalytic effect of the acid in this and other similar catalytic reactions is produced partly by the ions and partly by the undissociated acid.

In the experiments summarized below, the extent of hydrolysis was measured with a half-shade quartz-wedge compensation saccharimeter. The reaction mixtures were maintained at a temperature of 25° ± 0.02°. The rotations were observed at the same temperature as nearly as possible, the saccharimeter being enclosed in a wooden box for this purpose. Merck's glucose, after having been recrystallized three times from 95% alcohol, was used.

The measuring flasks were calibrated at 25° and the amount of glucose to be employed as space filler was obtained by preliminary experiments at this same temperature. All reaction mixtures containing glucose were allowed to stand until its rotation became constant before mixing. The cane sugar, glucose and exact weight of water needed for each experiment were put in a measuring flask and the acid in a glass-stoppered bottle; they were kept in the thermostat, and finally thoroughly and quickly mixed.

The inversion velocities of the following reaction mixtures were measured to find the effect of keeping the concentration of the water and sugar constant while varying the concentration of the respective acids employed as catalyzer. This was done by adding glucose to the weaker acid solutions to fill up the volume occupied by the acid removed.

In the tables, *t* denotes the time in hours,  $\alpha$  the observed rotation, and *k* the velocity constant calculated from the monomolecular equation  $k = \frac{1}{t} \log \frac{\alpha_0 - \alpha_\infty}{\alpha - \alpha_\infty}$ ,  $\alpha_0$  and  $\alpha_\infty$  denoting the initial and final rotations, respectively. The initial rotations (*t* = 0) were not observed but calculated by plotting on a large scale, the available values of  $\log (\alpha - \alpha_\infty)$  and extrapolating to *t* = 0, to find  $\log (\alpha_0 - \alpha_\infty)$  and hence  $\alpha_0$ .

The results show, for example, that the 0.5 N hydrochloric acid solution

inverts the cane sugar with a velocity 6.11 times as great as the 0.1 *N* and 62.36 times as great as does the 0.01 *N* solution. The results with the other acids are similar; in no case, does the expedient of adding an inert substance, glucose, in order to keep the concentration of the water and cane sugar constant while varying the concentration of the acid, produce any appreciable effect in yielding a numerical proportionality between the quantity of hydrogen ions employed as catalyzer and the inversion velocities.

Fairly wide differences for the degree of dissociation of the various acids have been used by various investigators, in calculating the catalytic effect of the hydrogen ions and the undissociated part of the acid. For purposes of comparison with the results obtained by Marshall<sup>9</sup> from Ostwald's sugar inversion measurements, the degrees of dissociation of hydrochloric, nitric and hydrobromic acids employed by him, have been used in calculating from the above measurements, the values of  $K_m$  and  $K_i$ , and the ratio  $K_m / K_i$ , which is the ratio between the catalytic effect of undissociated acid and that of an equal concentration of hydrogen ions. From the values of  $K_m$  and  $K_i$  obtained,  $K_m$  the molecular inversion velocity for the different concentrations has been calculated for comparison with that experimentally found.

0.01	0.850	....	0.1522	0.1600

The value of  $\alpha$  for 0.5 *N* sulfuric acid was calculated from the equivalent conductances as given by Kohlrausch<sup>4</sup> for a temperature of 18° after

<sup>9</sup> Marshall, *Am. Chem. J.*, 49, 353 (1913).

being corrected to 25° by Jones'<sup>10</sup> temperature coefficient. The values for the other two concentrations are the average given by Noyes.<sup>11</sup>

The agreement between the calculated and found values of  $K_n$  is of the same order as that calculated by Marshall from Ostwald's measurements. The values of  $K_i$  for the hydrogen ion, from the first three acids are the same, ( $K_i = 0.234$ ) but for sulfuric acid has fallen to  $K_i = 0.144$ . Likewise the activity of the nonionized acid, which is from 2.6 to 3.3 times that of the hydrogen ions for the three acids, hydrochloric, nitric and hydrobromic, is in the case of sulfuric only 1.24 times as great.

### The Effect of Neutral Salts.

Analogous experiments were carried out to find the comparative effect produced on the rate of inversion by a strong acid (Solution XIII), a strong acid together with a neutral salt containing a common ion (Solution XIV), and a strong acid together with an inert substance, glucose (Solution XV), the glucose occupying the same volume as the neutral salt in the preceding series. In this series also 57 g. of cane sugar was used, and the volume was 250 cc. In each solution the weight of nitric acid was 0.7875 g.

The effect produced on the inversion velocity by an amount of glucose occupying the same volume as the potassium nitrate is seen to be very slight. The increase in velocity produced by the neutral salt can to a very

<sup>10</sup> Jones, "Electrical Conductance," etc. *Carnegie Inst. Pub.*, 1912, p. 170.

<sup>11</sup> Noyes, "The Electrical Conductance of Aqueous Solutions," A. A. Noyes, *ibid.*, 63, 268 (1907).

little extent therefore be attributed to the fact that the volume of reaction mixture is reduced by the presence of the neutral salt. This is in agreement with the conclusions arrived at by McBain and Coleman,<sup>12</sup> who have shown in a number of cases that if the catalytic effect of the undissociated acid formed in the presence of neutral salts be taken into account the velocities of inversion are within 4% of the predicted rates.

### Summary.

The addition of an inert substance, to keep the concentration of water and cane sugar constant while varying the concentration of the acid, has no appreciable effect in producing a numerical proportionality between the quantity of hydrogen ions present and the inversion velocity of cane sugar.

The increase in velocity of cane sugar hydrolysis produced by a strong acid in the presence of a neutral salt of that acid, over the velocity produced by that acid alone, can to very little extent be attributed to the fact that the volume of the reaction is reduced by the presence of the salt.

On the assumption that both the undissociated and dissociated forms of an acid are catalytically active in cane sugar inversion, the values of  $K_i$  for the hydrogen ion from hydrochloric, hydrobromic and nitric acids have the same value ( $K_i=0.234$ ); the corresponding value for sulfuric acid is considerably lower ( $K_i=0.144$ ).

## THE VISCOSITY OF GELATIN SOLS.

By ROBERT H. BOGUE.<sup>1</sup>

Received January 3, 1921.

### Introduction.

A mathematical expression for the viscosity of two-phase systems was developed by A. Einstein<sup>2</sup> in 1906 and generalized by E. Hatschek<sup>3</sup> in 1910-1913. According to the latter investigator, the viscosity of all two-phase systems may fall in one of two possible conditions. So long as the particles of dispersed phase occupy so small a proportion of the total volume of the system that they do not touch each other, the increase of viscosity should be a linear function of the concentration only and independent of the size of the particles. In the derivation of his formula, the particles of dispersed phase are assumed to be spherical, undeformable, and

of smooth surface. These conditions are probably seldom attained, but a reasonable conformity to his formula has been found in the case of gamboge and mastic by Bancelin,<sup>4</sup> and in the case of starch by Harrison.<sup>5</sup>

Hatschek writes the equation,

$$\eta' = \eta (1 + 4.5 f) \quad (1)$$

when  $\eta'$  is the viscosity of the system,  $\eta$  the viscosity coefficient of the liquid or continuous phase, and  $f$  the ratio of the volume of the dispersed phase to the total volume of the system. The constant 4.5 has been given several different values, however, by different observers. Einstein first gave it a value of unity, and later changed it to 2.5. Bancelin found it to be 2.9.

Just as soon, however, as the ratio of the volume of the dispersed phase to the total volume of the system becomes so great that the particles touch each other, then the viscosity-concentration curve no longer remains linear, but becomes curvilinear. (The volume of the dispersed phase, as here used, includes the sum of the volume of the dispersed particles *per se* and the volume of the liquid or dispersion medium which has become associated with the dispersed particles in a solvated or hydrated condition.) The volume of the dispersed phase at the moment when the above condition is attained will be 74.04% of the total volume, according to Hatschek's calculations, and as the concentration becomes greater, the previously spherical particles will, in the case of an emulsion and an emulsoid at least, become dodecahedral; and if the system is now subjected to shear it will quickly assume a position in which such shear will take place entirely in the continuous phase. Under these new conditions, the viscosity is expressed by

$$\eta = (\sqrt[3]{A} / \sqrt[3]{A - 1})^3 \quad (2)$$

in which  $\eta$  is the coefficient of viscosity of the system, and  $A$  is the ratio of the total volume of the system to the volume of the dispersed phase. As we are unable directly to measure the volume of the dispersed phase of an emulsoid, we may obtain the value of  $A$  by a rearrangement of Equation 2; thus,

$$A = (\eta / (\eta - 1))^3, \quad (3)$$

and if the amount of dispersed substance is expressed in percentage, *e. g.*, total volume divided by dispersed weight, then this value, which Hatschek calls  $A'$  should bear a constant ratio to  $A$  which is total volume divided by the dispersed volume, or  $A' / A = K$ .

<sup>4</sup> Bancelin, *Kolloid Z.*, 9, 154 (1911).

<sup>5</sup> Harrison, *J. Soc. Dyers Colorists*, 27, 84 (1911).

This has been tested by Hatschek using the data of Botazzi and d'Errico<sup>6</sup> upon glycogen sol, and of Chick and Martin<sup>7</sup> upon sodium caseinogenate sol. Hatschek finds the value of  $K$  to be nearly constant at about 2.1 between the concentrations of 30 and 45 in the glycogen sol, and at about 9.5 between the concentrations of 6.04 and 9.39 in the case of the casein sol.

As expressions of the type developed by Hatschek are fundamental and must inevitably lead to a better understanding of the complex conditions obtaining in colloid sols, it becomes desirable that experimental data be accumulated which will tend either to confirm the hypotheses upon which the formulas are based, or to indicate points which will require mathematical revision. With this end in view, the following experiments have been conducted upon gelatin sols.

### Experimental.

A high grade of gelatin was used in concentrations varying by small increments from 0.01 to 30.00%. In order that comprehensive data might be obtained the viscosity of gelatin in five different conditions was studied. In Series 1 the gelatin was dissolved in distilled water giving a solution whose hydrogen-ion value in 1% concentration was  $1.5 \times 10^{-6}$ , so that the solute was essentially calcium gelatinate. In Series 2, an iso-electric gelatin was obtained by screening gelatin powder, taking that portion which passed a 40-mesh screen but was retained by one of 60 mesh, soaking it for an hour in hydrochloric acid of 0.0078  $N$  concentration, filtering, and washing several times with distilled water. A 1% solution had a hydrogen-ion concentration of  $2 \times 10^{-5}$ , the value of gelatin at its iso-electric point. Series 3 was treated in a similar way to the preceding, except that the acid used was of 0.031  $N$  concentration. It had previously been found that such treatment resulted in the maximum of swelling and of viscosity, while at the iso-electric point these properties possessed their minimum values. Series 4 and 5 were treated similarly to Series 2 and 3 respectively, except that the acids in which they were allowed to soak were not removed, but the gelatin was dissolved and diluted to the desired concentration in the presence of the large excess of acid.

The temperature selected for all determinations was fixed at 35° in order that no complications due to an equilibrium between what Smith<sup>8</sup> calls sol form *A* and gel form *B* should arise. At 35° the gelatin is, according to Smith, entirely in the condition of the sol form *A*. The temperature was maintained constant by the immersion of all samples and appa-

ratus in a thermostat, the average fluctuation of which was  $\pm 0.05^\circ$  at  $35^\circ$ .

All viscosity measurements, with three exceptions, were made by the use of an Ostwald capillary viscosimeter, employing 3 cc. for each determination. Duplicate runs were made in each case, and the average used in the calculations. The variation between duplicate measurements was rarely more than 0.2 to 0.3 second, even in the more viscid concentrations. The viscosity of Expts. 23, 24 and 25 of Series 1 was measured by the use of a MacMichael viscosimeter.

The data obtained are given, in part, in the following tables. The first column of Table I shows the percentage concentration,  $C$ , of the gelatin sol; in Col. 2 is given the coefficient of viscosity, water being taken as unity; in Col. 3 the values calculated for  $A$  by Equation 3; in Col. 4 the value for  $A'$ , *e. g.*, 100 divided by dispersed weight in percentage; and in Col. 5 the ratio of  $A'/A$ . The remaining two columns will be discussed later.

Fig. 2.—Relation of viscosity to concentration in gelatin solutions.

for the five series. In Fig. 3 the values of  $K$  are plotted against gelatin concentration.

### Discussion.

The data presented above reveal several points of interest, the most important being the failure to obtain a real constant for the ratio of  $A'/A$ . In each of the five series studied the value of this ratio rises to a maximum

with increasing concentration, and then as regularly, but more slowly, drops. Within a range of several per cent. the value of  $K$  varies but little, but the fact that, although the variation is small, it is nevertheless perfectly regular (except in special cases as noted below) can be interpreted in no other way than that a real constant is not obtained under the conditions of the experiment, and the variation may not be regarded as an experimental error.

In this connection it must be pointed out that in the calculations of Hatschek upon work reported by Botazzi and d'Errico on glycogen sols, and by Chick and Martin upon casein sols, the same regular rise to a maximum, in the value of  $K$ , followed by a similar regular drop, is observed. Hatschek makes no mention of this fact, however, and apparently regards the values attained as *constant* in the customary sense of the term. In Series I it will be observed that on carrying the concentration of the gelatin up to 30% the value of  $K$  had dropped from a maximum of 9.57 to 3.28. In experiments upon cellulose nitrate dissolved in 30% camphor-alcohol Sherrick<sup>9</sup> found similar results; *e. g.*, at a concentration of 2.54% his value for  $K$  was 34.64, and on increasing the concentration above that value the value of  $K$  also dropped as follows.

Fig. 3.—Variation in  $K$  with concentration of gelatin.

Concentration g. per 100 cc.	Absolute viscos- ity of sol.	Absolute viscos- ity of solvent.	A.	$A'$ .	$A'/A$ .	Percentage vol- ume of sol. occu- pied by solvated disperse phase.
2.54	23.03	0.96	1.1364	39.37	34.64	88.00
4.00	205.21	0.96	1.0142	25.00	24.65	98.6
7.50	565.65	0.96	1.0050	13.33	13.27	99.5
10.00	960.95	0.96	1.0030	10.00	9.97	99.7
12.00	1372.30	0.96	1.0020	8.33	8.31	99.8
15.00	3201.00	0.96	1.0010	6.666	6.66	99.9

The value of  $K$  may be analyzed as follows.

$$\frac{A'}{A} = \frac{\text{total volume}}{\text{dispersed weight}} \times \frac{\text{dispersed volume}}{\text{total volume}} = \frac{\text{dispersed volume}}{\text{dispersed weight}}$$

In other words  $K$  represents the volume occupied by unit weight of the dispersed phase. At low concentrations the structure upon which the formula is based is not present and accordingly the above statement

<sup>9</sup> J. L. Sherrick (Mellon Institute); personal communication.

may be applied only to more concentrated sols, but as soon as the necessary concentration is reached, it would be expected that the formula would accurately represent the result until such an amount of dispersed phase was present that there no longer was sufficient water, or other dispersing medium, present to allow the solvate action to proceed to its maximum. As soon as that concentration was reached the volume occupied by unit weight of dispersed phase ( $K$ ) would thereafter decrease with increasing concentration. But an examination of the data shows that the total volume of dispersed phase ( $K \times C$ ) has in no case except in the last experiment listed in Series 1 reached a value approaching the total volume of the system. Indeed, in the present experiment the maximum value of  $K$  is reached when the total volume of dispersed phase is only 32.8% of the total volume of the system in the case of the gelatin chloride, and 57.4 and 62.4% respectively in the other series. In the cases of the glycogen and casein sols previously mentioned the maximum value of  $K$  is obtained when the volumes of dispersed phase are 77.4 and 68.6% respectively of the volumes of the systems. In every case cited the value of  $K$  drops regularly from this point. Only in the experiments of Sherrick may this drop be explained as due to an actual insufficiency of dispersing medium for in his determinations the volume of dispersed phase is already 88.00% at the lowest concentration which he employed, and very quickly rises above 99%.

It is, therefore, pertinent to raise the question: Why does the volume occupied by unit weight of dispersed phase decrease with increasing concentration after attaining a definite maximum? (We are admitting the validity of Hatschek's postulations by which he formulated his equations, and therefore assume the value  $A'/A$  to express correctly the volume per unit weight of dispersed phase.) Two possible causes may bring about this decrease in volume; the increasing surface tension of the dispersion medium, or an actual reversal of phase. From a consideration of the laws of surface tension it becomes evident that as the number of particles of dispersed phase (the concentration) increases, the film of liquid separating them must become ever thinner and thinner in order to maintain its continuity. As this process continues the free surface of the dispersion medium becomes ever greater, and this may take place only at an expenditure of energy, *e. g.*, it is opposed by the surface tension of the liquid, and the greater the surface under stress, the greater will be the force opposing further increase in free surface. We may regard this force as entering into competition for the liquid against the solvate potential of the dispersed particles. An equilibrium must therefore be attained between these two forces at any given concentration.

Surface tension (of dispersion medium)  $\rightleftharpoons$  Solvation potential (of dispersed phase).

An excess of liquid will increase the solvation potential of the dis-

persed phase and an excess of dispersed particles will increase the surface energy of the dispersion medium.

The extent to which the surface tension may influence the solvation, and consequently the volume occupied by unit weight of dispersed phase, is shown to be a function of the percentage volume of the dispersion medium and if we may regard that volume of dispersion medium at which the dispersed phase reaches its maximum volume per unit weight as the point of neutrality in the above equation, the two forces there being equal, then the increasing effect of the surface tension is found to follow very nearly the empirical expression,

$$\sqrt[3]{V_m^0} - \sqrt[3]{V_m} = s, \quad (4)$$

where  $V_m^0$  is the volume of dispersion medium when  $A'/A$  is at its maximum,  $V_m$  is the volume of the dispersion medium at any other concentration, and  $s$  is the decrease in volume per unit weight of dispersed phase at the concentration  $V_m$ . Then

$$K \pm s = k_s, \quad (5)$$

where  $k_s$  is a constant corrected for surface tension.  $s$  is added at concentrations of dispersed phase greater than that at  $V_m^0$ , and subtracted at the lower concentrations. In Table I, Col. 6 shows the value of  $V_m$  and Col. 7 the value of  $k_s$ . The values of  $K$  and  $k_s$  for the five series are shown in Table II. In Fig. 4  $k_s$  is plotted against gelatin concentration.

In the case of the gelatin dissolved in 0.0078 *N* and in 0.031 *N* hydrochloric acid the uniform variations and consistency of direction which characterize the curves for the gelatin chloride, the iso-electric gelatin, and the calcium gelatinate, are not obtained. This is true for both the  $K$  and the  $k_s$  concentration curves. The reason for this difference in behavior of these two gelatins is not obvious, but it undoubtedly is connected with the presence of the free acid in the solution, and the variation, by the alteration in gelatin concentration, of the hydrogen-ion concentration of the system. Further study will be made of these special cases.

If the process of stretching out the thin film of dispersion medium by increasing concentration is continued beyond a certain point, this film

Fig. 4.—Variation in  $k_s$  with concentration of gelatin.

must break and cease to be continuous. When this happens there will probably follow a reversal of phase. The previously dispersed phase will become continuous, and the former dispersion medium will become dispersed. When this happens the formula of Hatschek would no longer hold good, as the system has suffered an abrupt change not accounted for in his equations. This fact might also explain the failure of Hatschek's  $K$  to remain constant, but it would scarcely be expected that a reversal of phase would occur at the low concentrations where the value of  $K$  begins to decline in gelatin sols.

Another point which is well brought out in the present work, and is made manifest by a comparison of the several columns in Table II, and by the curves in Fig. 1, is the wide variation in the viscosity of gelatin in different states of hydrogen-ion concentration, and in the volume occupied by unit weight of gelatin in these different states. As shown in Table II, the maximum volume per unit weight of gelatin chloride, at a hydrogen-ion concentration of  $3.1 \times 10^{-4}$  is 10.96, and is attained at a gelatin concentration of 3%, while in the case of iso-electric gelatin the maximum volume per unit weight is only 8.92 and is not reached until a concentration of 7% of gelatin is present. The untreated gelatin, which is calcium gelatinates of a hydrogen-ion concentration of  $1.5 \times 10^{-6}$ , attains a maximum of 9.57 at a concentration of 6%. It is especially interesting that in the case of the gelatin which is treated with acid, and the excess of acid *not* removed, the maximum volume reached, and the concentration of gelatin at that point, are identical with those of the iso-electric gelatin. In other words an excess of acid retards solvation in the sol state. That viscosity and solvation run parallel is evidenced by the fact that the higher the viscosity, the higher also is the value of  $K$ .

### Summary.

Experiments have been carried out upon gelatin sols to determine accurately the relation between viscosity and concentration. The data obtained have been applied to Hatschek's formula for the viscosity of emulsoids, and it is shown that the value  $A'/A$ , representing the volume occupied per unit weight of dispersed phase, is not a constant with varying concentration, but that this value rises regularly to a maximum, and thereafter regularly declines with increasing concentration. This behavior is noted also to exist in the cases of other colloids. A tentative explanation is presented based upon the effect which increasing concentrations of dispersed phase will have upon the surface tension of the dispersion medium. Assuming the equilibrium,

surface tension  $\rightleftharpoons$  solvation potential,

an empirical relation is developed which, with a fair degree of accuracy, defines the equilibrium. At very high concentrations a reversal of phase

probably occurs, at which point no expressions yet developed adequately represent the relations involved.

A high degree of solvation is shown to be indicated by a high coefficient of viscosity, *e. g.*, solvation and viscosity are parallel functions.

Iso-electric gelatin at a hydrogen-ion concentration of  $2 \times 10^{-5}$  is shown to have the lowest viscosity and the lowest degree of solvation, gelatin chloride at a hydrogen-ion concentration of  $3.1 \times 10^{-4}$  the highest, and calcium gelatinate at a hydrogen-ion concentration of  $2.5 \times 10^{-6}$  is intermediate.

If an excess of acid is allowed to remain in the gelatin solution, even though the acid be of very low concentration, the viscosity and degree of solvation will be retarded.<sup>10</sup>

PITTSBURGH, PA.

<sup>10</sup> In comment upon the above paper Dr. Emil Hatschek has written the author as follows.

"I think that my method of attack is correct in principle, but it involves several assumptions which go perhaps too far in the direction of simplifying the phenomena. One is obviously the assumption of spherical particles which, on crowding, become simple polyhedra. The gelatin molecule or aggregate is probably far from being of so simple a shape. If we had some information regarding it, the matter could probably be dealt with again, but, in the absence of such information it would be a fruitless mathematical exercise to investigate nonhomogeneous assemblages. That the formula applies, on the other hand, to deformable particles of a shape far different from the simple spherical, but still very symmetrical, is proved by the surprising closeness with which it fits red blood corpuscles. (E. Hatschek, *Kolloid Z.*, 27, 163 (1920).)

"The second point is the inconstancy of the degree of hydration or, generally, solvation. I had noticed this, in trying to fit the formula to rubber, etc., sols, but have not published anything in that respect. The simplest explanation seems to me this: the formula assumes that the continuous phase is *pure dispersion medium*, and that all the colloid is in the disperse phase, associated with some dispersion medium. Now this is probably also an undue simplification of the conditions. It is probable that the dispersion medium also contains some of the colloid, and it seems to me at least possible that the proportion may change, *i. e.*, the ratio, colloid in disperse phase: colloid in continuous phase, may become smaller with increasing concentration.

Both suggestions you make are very interesting. The interfacial tension between the two phases, being due only to the difference in concentration, can be very small only, but that would not prevent its defining an equilibrium. The suggestion that a reversal of phases may take place is ingenious, but one would like to have some further evidence to support it. It seems to me it would almost certainly entail a break in the viscosity-concentration curve, of which there is no indication. There is also the possibility that the hydration may really decrease at higher concentration, as it does with some true solutes. I think a clue to the distribution of water may perhaps be afforded by the solubility of gases, or liquids like ether, in gelatin sols—but the results published so far, particularly by A. Findlay, seem very difficult of interpretation."

## AN ATTEMPT TO PREPARE NITRO-NITROGEN TRICHLORIDE. II. THE CONDUCT OF MIXTURES OF NITROGEN AND CHLORINE IN A FLAMING ARC.

BY WILLIAM ALBERT NOYES.

Received April 11, 1921.

Eight years ago<sup>1</sup> an account was given of experiments designed in the hope of preparing a nitro-nitrogen trichloride in which the chlorine atoms would be negative and which would hydrolyze normally to hydrochloric and nitrous acids in contrast with the ordinary nitrogen trichloride in which the chlorine atoms are positive and show a tendency always to separate in such a manner as to be replaced by hydrogen, while the chlorine atoms have twice the oxidizing power of the atoms of free chlorine.<sup>2</sup>

Since that article was published evidence for the composite nature of chemical atoms has accumulated rapidly and chemists seem ready to accept the view that atoms are composed of electrons and positive nuclei held together by either static or dynamic electrical forces or by a combination of the two. The distinction between nuclear electrons, which remain unchanged in their relation to the nucleus of the atom, and valence electrons, which take part in some manner in reactions between atoms, seems also to be universally accepted by those who discuss questions of this character at all.

Three more or less distinct hypotheses have been proposed to account for the mechanism by which valence electrons hold atoms in combination.

1. J. J. Thompson,<sup>3</sup> who was the first to state the concept of valence electrons clearly, proposed the hypothesis that atoms consist of a sphere of positive material with electrons inside and valence electrons transferred completely from one atom to the other in chemical combination. Nearly all of the purely chemical discussion by Falk and Nelson, Fry, Jones, Stieglitz and others has made use of this simple notion of the transfer of electrons.

2. Ramsay<sup>4</sup> suggested that an electron might serve as a connecting link between atoms. In almost or quite the last paper that he published<sup>5</sup> he described an apparatus designed to show that atoms may be held in combination by the magnetic attraction between rotating electrons. Bohr<sup>6</sup> also supposed that atoms may be held in combination by elec-

trons rotating about the line joining the centers of the atoms, the attraction being static rather than magnetic. Parson<sup>7</sup> has also developed an elaborate magneton theory

3. G. N. Lewis,<sup>8</sup> in an hypothesis which has been elaborated and brought to the attention of a wide circle of chemists by Irving Langmuir,<sup>9</sup> makes the following suppositions.

(a) Every atom has a central kernel composed of positive units and electrons, the latter being, of course, the nuclear electrons referred to above. X-rays seem to be emitted from these nuclear electrons.

(b) The central kernel is identical with the atom and has a zero charge for elements of the zero group. It has a unit positive charge for hydrogen and an excess of positive charges varying (by whole units) from 1 to 7 for other atoms. The words in parenthesis are not included in the statement of Professor Lewis but seem to be justified by the experimental evidence.

(c) Neutral atoms have an outer shell of electrons varying from 1 to 8. The positive charge of the kernel is exactly balanced by the negative charges of these electrons.

At the April meeting of the National Academy of Sciences, R. A. Millikan gave evidence from the spectrum lines beyond the ultra-violet which affords very strong support for this part of the hypothesis and which seems to prove that these electrons of the outer shell are very far from the center of the atom in comparison with the nuclear electrons which emit X-rays. It seems evident that the electrons of the outer shell are the valence electrons.

(d) Atoms may give up electrons from the outer shell, forming positive ions, or take electrons from other atoms, forming negative ions, 7 or two atoms may hold 2 (or 4) electrons in common forming "non-polar" compounds.

(e) It seems to follow from the hypothesis as stated that no atom can be in direct union with more than 4 other atoms. It is at this point that the hypothesis differs most radically from theories of valence previously current. It does not seem to agree very well with the existence of such compounds as  $\text{PCl}_5$ ,  $\text{SF}_6$ ,  $\text{S}(\text{OH})_6$ , etc., though Langmuir has attempted an explanation of some of these.<sup>10</sup> It does not give a very satisfactory picture of the apparent regular increase of valence from 1 to 7 in the series of oxides  $\text{Na}_2\text{O}$ — $\text{Cl}_2\text{O}_7$  and in the corresponding acids. According to the hypothesis of Lewis this series of oxides is represented as follows:

An examination of these formulas makes it clear that in phosphorus pentoxide and in sulfur trioxide two of the double unions of the older formulas have become single unions while in chlorine heptoxide three double unions have become single unions.

The hypotheses of Bohr and of Lewis agree with the evidence of the scattering of  $\alpha$ -particles by thin films presented by Rutherford.<sup>11</sup> He

<sup>8</sup> Lewis, *THIS JOURNAL*, 38, 762 (1916).

<sup>9</sup> Langmuir, *ibid.*, 41, 868 (1919).

<sup>10</sup> I understand that Lewis assumes a higher value than 4 in some cases but I do not know that such a statement has been published.

<sup>11</sup> Rutherford, *Phil. Mag.*, 21, 669 (1911).

considers that this evidence has demonstrated that the positive nuclei of atoms have a volume very small in comparison with the effective size of the atoms. J. J. Thompson's hypothesis of a sphere of positive material with embedded electrons has, therefore, been abandoned. The question whether there is a transfer of an electron from one atom to another in all forms of chemical combination or whether this occurs only in the so-called "polar" compounds, and the question whether atoms are held together by a single electron or by pairs of electrons may well be considered as still open.

Nitrosyl chloride,  $\text{NOCl}$ , hydrolyzes to nitrous and hydrochloric acids. According to the hypothesis of Professor Lewis, the two electrons which hold the atoms of nitrogen and chlorine together remain with the chlorine atom in the decomposition of the nitrosyl chloride, but they remain with the nitrogen atom in the decomposition of nitrogen trichloride, or of chloroamine,  $\text{NH}_2\text{Cl}$ . The difference in conduct may be explained as due to the oxygen atom in the nitrosyl chloride but, if it were possible to prepare an isomeric nitrogen chloride in which the chlorine would tend to separate as a chloride ion, the hypothesis that there is a pair of electrons between the atoms would become far less probable. The question seems one of sufficient theoretical importance to justify the considerable amount of time which has been spent on the experiments described in this paper.

Nitrogen and oxygen combine at a very high temperature to form the endothermic compound, nitric oxide, in which the nitrogen is usually assumed to be positive and the oxygen negative. It seemed possible that a nitrogen dichloride in which the chlorine would be negative might be formed in a similar manner. So far as the writer is aware no one had ever tried the experiment. The first experiments, in which an ordinary induction coil and heavy platinum wires were used, were begun about 7 years ago and the study of the problem has been continued at intervals up to the present. The final result of the investigation is negative and it is unnecessary to describe in detail a dozen or more different modifications of the apparatus used.

The two forms which were longest used and which seem to be best adapted for such a purpose are shown in the figures.

The air was displaced by nitrogen passed in from the top and liquid chlorine was condensed in the small bulb at the bottom. The apparatus was then closed and a circulation of the nitrogen mixed with chlorine, at the vapor pressure of liquid chlorine at the temperature of carbon-dioxide snow mixed with alcohol, was produced by the heat from the discharge in the bulb and by cooling the side tube with ice. The electrodes were attacked by the chlorine and it was never possible to continue the experiments more than a few hours before they were perforated. In a considerable number of experiments the periods of operation were from 1 to 3 hours

Fig. 1.

Fig. 1 shows a bulb with a capacity of about 350 cc. Two hollow platinum electrodes with heavy platinum-iridium tips were used. Between these electrodes an alternating discharge was produced by a Thorardson transformer rated at 110/10,000 volts. The electric flame was spread to an area of 4 to 5 sq. cm. by a very powerful electro-magnet having the poles properly placed on the two sides of the bulb.

and in two experiments for 8 and 10 hours respectively. At the close of the run the chlorine was allowed to evaporate and pass through water to hydrolyze the product and the gases remaining in the apparatus were driven through the water by nitrogen or air. The nitric acid formed in this way was determined by reduction to ammonia.

Careful blank tests for compounds of nitrogen were run on the mixture of the two gases placed in the tube in the usual manner, as well as on the water used for hydrolysis, with absolutely negative results. The first four runs with this apparatus lasting from 1 to 4 hours have values for combined nitrogen ranging from 0.5–1.0 mg. The next two of 3.5 and 2 hours duration gave 0.2 and 0.3 mg; while in the seventh run lasting 8 hours, analysis indicated only 0.07 mg. From the well-known difficulty in removing moisture from glass it seems probable that the yields

were due to interaction between nitrogen in the arc with either oxygen or hydrogen from decomposed moisture. With the gradual elimination of this absorbed water the yields decreased. In the eighth run 2 or 3 drops of water were added to the chlorine forming a small visible lump of ice. The vapor pressure of the ice is small at the temperatures used, below  $0^{\circ}$ , so that but little escaped, and during a 10-hour run only 0.17 mg. of nitrogen was brought into combination.

In the endeavor to "freeze out" any compound of nitrogen and chlorine that might be formed, an apparatus was made where the arc, spread as before, was allowed to strike between platinum-iridium electrodes close to the surface of liquid chlorine in an atmosphere of chlorine and pure nitrogen.

Fig. 2.

A quartz tube protected the glass walls from the heat of the arc. Four completed runs were made lasting from 1 to 2.5 hours with the formation of no appreciable amount of nitrogen compound. Other forms of apparatus designed to bring the gases after leaving the arc more quickly into contact with a cooled surface gave negative results with a spread arc. A silent discharge likewise gave negative results.

The last form of apparatus to be used, and the most satisfactory, is shown in Fig. 2.

Two platinum wires, A B, 18 cm. long and 0.5 mm. in diameter, but made heavier at the top by putting 3 or 4 pieces of the wire together, were supported from the platinum connections C and D and held in place by the circular rod of Pyrex glass bearing platinum wires welded to the longer wires and by a U-shaped rod of Pyrex glass at the bottom.

By this arrangement contact of the electric flame with the glass supports was completely avoided. The wires were placed about 4 mm. apart at the bottom and 15 mm. apart at the top. These distances were fixed by careful preliminary experiments. The distance at the bottom must be such that a discharge from the Thorardson transformer will pass between the wires and immediately begin to travel up the wires as the gases above the discharge become heated. If the distance is too great the discharge will not pass and if too small it remains at the bottom and soon melts the ends of the wires. The distance at the top is such that when the discharge reaches that point a flaming arc is produced. In a part of the experiments (1-10) recorded in the table (p. 1780), wires 50 cm. long, 4 mm. apart at the bottom and 20 mm. apart at the top, were used. With this form of apparatus the arc would break when it reached the top, and start again at the bottom. This was more difficult to regulate than the stationary arc. Dr. Rideal suggested this form of apparatus and we understand that it has been used in commercial practices.

The nitrogen was prepared by passing a mixture of air and purified hydrogen, from a Kipp generator, through a hard glass tube about 80 cm. in length placed in a combustion furnace. The tube was filled at first with copper oxide, and about half of this was reduced to metallic copper. It is easy to regulate the rates for the hydrogen and air so that the relative amounts of copper and copper oxide remain nearly constant; and if these are moderately hot it is impossible for either oxygen or hydrogen to pass beyond the tube. The nitrogen was dried with conc. sulfuric acid and phosphorus pentoxide. Chlorine was prepared by warming a mixture of sodium dichromate and hydrochloric acid and was condensed in a bulb surrounded by carbon-dioxide snow and alcohol and introduced through a side tube sealed to the tubes between the sulfuric acid bottle and the phosphorus pentoxide tube.

All parts of the apparatus were sealed together. In the last experiment where the negative result was most conclusive, a current of nitrogen was passed through the apparatus at first for 5 hours and it was then surrounded with asbestos and heated from below to 100° or 130° while the current of nitrogen was continued and the arc maintained for 18 hours longer. The chlorine was then introduced and condensed in the lower bend of the apparatus by surrounding this with carbon-dioxide snow and alcohol. Nitrogen was again passed through the apparatus for some time and the arc was operated for 51 hours. The upright tube at the left side of the apparatus was about one cm. in diameter, and during the operation of the arc the circulation of the gases through the system was sufficiently rapid so that the tube on the right through which the cold gases rose into the larger tube became covered with frost.

At the close of the experiment the carbon dioxide snow was removed and the chlorine was allowed to evaporate and pass through the hydrolysis tube shown in Fig. 3. The spiral tube is 185 cm. in length and only 2 mm. in diameter. If 2 or 3 cc. of water is placed in the apparatus, gas entering at A pushes short columns of water around the spiral to B, from which point the water is returned through the upright tube to C. This secures a very effective contact between the gas and liquid with the use of a very small amount of water.

Fig. 3.

If any nitro chloride of nitrogen were formed it would be converted to nitric acid by the chlorine passing the hydrolysis apparatus with it.  $\text{NCl}_3 + \text{Cl}_2 + 3\text{H}_2\text{O} = \text{HNO}_3 + 5\text{HCl}$ , or  $2\text{NCl}_2 + 3\text{Cl}_2 + 6\text{H}_2\text{O} = 2\text{HNO}_3 + 10\text{HCl}$ . The ratio of nitrogen to chlorine, irrespective of the composition of the nitrogen chloride, would be 1:5. It was shown that pure chlorine left only the merest trace of combined chlorine in the water when it was passed through the spiral and followed by nitrogen or air.

If nitrosyl chloride were formed in the apparatus because of the pres-

ence of a trace of oxygen or of moisture the ratio of nitrogen to chlorine would be 1:3:  $\text{NOCl} + \text{Cl}_2 + 2\text{H}_2\text{O} = \text{HNO}_3 + 3\text{HCl}$ .

If the vapor of ordinary, ammonio-nitrogen trichloride is passed through the spiral tube it was demonstrated that practically no hydrolysis occurs. On the other hand, if the vapor is passed through conc. hydrochloric acid, ammonium chloride and chlorine<sup>12</sup> are formed. The products formed in the arc were tested in that way with negative results.

After the completion of an experiment the water in which the products were hydrolyzed was diluted to a standard volume and the combined nitrogen and chlorine were determined in aliquot portions. The nitrogen was determined by reduction in an alkaline solution with Devarda's alloy, and the chlorine by precipitation with silver nitrate. The results of 13 experiments were as follows.

Expt.	No. of hours arc was operated.	Mg. atoms. N.	Mg. atoms. Cl.
1	10	1.54	4.20
2	20	0.11	0.113
3	18	0.96	2.96
4	20	0.44	1.05
5	30	0.66	2.80
6	14	0.12	0.35
7	10	0.20	0.60
8	10	0.05	0.18
9	6	0.02	0.05
10	8	0.01	0.07
11	38	0.06	0.22
12	53	0.05	0.57
13	51	0.006	0.024

In the earlier experiments, in which the extreme care of the later experiments to remove traces of oxygen and moisture was not observed, appreciable amounts of combined nitrogen were formed, but the ratio of nitrogen to chlorine was much less than 1:5 and in those cases where most nitrogen was formed approximated 1:3. It seems quite certain that the compound present in these cases was nitrosyl chloride. The evidence of the later experiments seems practically conclusive as demonstrating that if nitrogen and chlorine combine at all in the flaming arc the compound is decomposed as it escapes from the zone of heat.

In all of the experiments with platinum electrodes a grayish-brown deposit was formed on the walls of the tube. Expts. 6 to 10 of the table were carried out consecutively. The solution obtained by washing the apparatus out with water, contained 0.75 mg. atoms of combined nitrogen. The wash solutions from Expts. 11 and 12 contained 0.33 mg. atom, while that from the last experiment contained only 0.02 mg. atom of combined nitrogen.

<sup>12</sup> Noyes, *THIS JOURNAL*, 42, 2173 (1920).

The ratio of platinum to chlorine was also determined in the solutions. In the last experiment the atomic ratio was 1:3.6, indicating a mixture of platinic chloride,  $\text{PtCl}_4$ , with a little platinous chloride. In two earlier experiments the atomic ratios were 1:5.76 and 1:5, indicating the presence of chloroplatinic acid. The hydrochloric acid to form this probably came from the interaction of moisture, chlorine and nitrogen:  $\text{N}_2 + 2\text{Cl}_2 + 2\text{H}_2\text{O} = 2\text{NOCl} + 2\text{HCl}$ .

Several experiments were tried with carbon electrodes. The results were similar, but appreciable amounts of a white solid and of a colorless liquid were formed, doubtless carbon hexachloride and carbon tetrachloride.

To test the efficiency of the apparatus a run was made with air passing through it at the rate of 3.6 liters per hour. The oxides of nitrogen condensed almost completely in the lower part surrounded by carbon-dioxide snow and alcohol, as colorless crystals of nitrogen tetroxide, with only a little blue nitrous anhydride. About 30 mg. atoms of combined nitrogen were obtained in 2 hours—250,000 times as much as was obtained in the same time in the last experiment with nitrogen and chlorine.

Experiments were also tried with a very efficient ozonizer of Pyrex glass, consisting of two concentric tubes 55 to 60 cm. long and 2.8 and 3.7 cm. in diameter, respectively. The inner tube was filled with a solution of sodium sulfate and the outer tube was surrounded with the same electrolyte. A copper spiral running to the bottom of the inner tube and another wound around the larger tube furnished the connection with the terminals of the Thorardson transformer. When the latter was connected with the 110 volt circuit, quantities of ozone were produced in air passed between the tubes but no combined nitrogen was found. With 220 volts there was a crackling sound with a blue glow, and a large number of streamers appeared between the walls of the tubes. Under these conditions air passed through the apparatus gave 0.15 mg. of combined nitrogen in 30 minutes but a mixture of nitrogen and chlorine passed for 6 hours gave no combined nitrogen. A negative result was also obtained with the conditions which gave ozone but no combined nitrogen.

When active nitrogen prepared by Strutt's method was passed over chlorine at the temperature of liquid air no combination occurred.

### Summary.

1. It has not been found possible to prepare either a nitro-nitrogen chloride or ordinary nitrogen trichloride by passing a mixture of nitrogen and chlorine through a flaming electric arc.

2. So far as negative results have value, the experiments favor Professor Lewis's hypothesis that electrons are held jointly by two atoms

rather than the view that electrons are transferred from one atom to the other when atoms combine.

I wish to express my appreciation of the valuable assistance of L. C. Johnson, B. R. Honovski, F. O. Anderegg, A. B. Haw, and G. H. Coleman in carrying out the experiments described in this paper.

## VAPOR PRESSURES OF AQUEOUS SOLUTIONS OF NITRIC ACID.

BY WILLIAM C. SPROESSER AND GUY B. TAYLOR.

Received April 14, 1921.

The partial pressures of water and nitric acid vapors in equilibrium with all concentrations of aqueous nitric acid possess scientific interest and are practically useful to the acid industry. Burdick and Freed<sup>1</sup> have recently supplied data for concentrations ranging from 24% to 70% nitric acid at 25°, 50°, and 75°. The present investigation had as its object the extension of similar data to 100% nitric acid and over a wider temperature range. The dynamic method chosen did not prove suitable for concentrations above 80%, owing to thermal decomposition of nitric acid vapor. The measurements covered the range from 20 to 90% at temperatures from 0° to 80° and, therefore, considerably extend the range, making it possible to draw a series of curves showing the acid composition of minimum vapor pressure within these temperature limits.

### Experimental.

The apparatus is shown in Fig. 1. Water from the reservoir A was siphoned into the calibrated bottle B, displacing a known volume<sup>2</sup> of air and forcing it through the dryer C, the carbon dioxide-remover F, the three saturators D, and the absorbers E. The dryer C was a Friedrichs "spiral" gas-wash-bottle containing conc. sulfuric acid. The U-tube F was filled with soda lime. The saturators D were special forms of spiral wash-bottles. In the last bottle a small accurate Anschütz thermometer, 3, was sealed to record the temperature, which was maintained constant to  $\pm 0.1^\circ$ . The three saturators were filled with nitric acid of known composition, fused together, and placed in the Freas constant-temperature oven G. The ground-glass joint, 4, connected the absorbers E to the rest of the system. The whole apparatus was always set up so that nitric acid, liquid and vapor, came in contact with glass only. To avoid condensation in the tube and ground joint protruding from the oven, an electrically heated wire-spiral was placed about the ground joint, 4, to keep the joint warm. The U-tube E, filled with solid sodium hydroxide and followed by two or more such tubes (not shown) containing as well, layers of phosphorus pentoxide on glass wool, was used to absorb the effluent vapors.

<sup>1</sup> Burdick and Freed, *THIS JOURNAL*, 43, 518 (1921).

<sup>2</sup> Calculated from the volume of the bottle, temperature and pressure within the bottle, and the barometric pressure.

ARRANGEMENT OF APPARATUS USED TO DETERMINE  
VAPOR PRESSURES OF NITRIC ACID SOLUTIONS.

After ascertaining the gain in weight of the U-tubes, the nitric acid absorbed by the alkali was determined by the Devarda method and nitrite was estimated by permanganate when found to be present. The results at temperatures from  $35^{\circ}$  to  $82^{\circ}$ , were obtained with this apparatus.

The method used for measurements at  $0^{\circ}$  was somewhat different from that described above. Air was purified from carbon dioxide and dried by passing in succession through a caustic solution and conc. sulfuric acid. The purified air was then bubbled through the saturators, which were entirely immersed in ice-water. Leaving the saturators, the air was passed in succession through (1) a Vanier bulb containing a known amount of standard caustic solution, (2) a large U-tube containing stick sodium hydroxide, at the exit end of which were several layers of phosphorus pentoxide on glass wool, and finally (3) a gas meter accurate to 0.001 cu. ft. The experiments were conducted in a constant-temperature room in order to determine accurately the volume of air passed through the saturators. At the exit end of the saturators there was a pressure of about 10 mm. mercury (above atmospheric) and in the vapor-pressure calculations a correction was made for this added pressure.

Equilibrium was assured at all temperatures by the usual expedient of varying the rate of air flow. Much faster rates than those used in any of the final experiments gave the same results.

### Discussion of Results.

Table I summarizes the experimental results, giving averages of duplicate runs. The vapor pressures were calculated from the data in the usual manner, *i. e.*, the volume of air and weights of water and nitric acid were calculated to volumes under standard conditions, from which mol fractions were derived. Mol fraction multiplied by the measured pressure prevailing over the solution in the last saturator bottle gave the respective partial pressures. This method of calculation assumes that both water and nitric acid vapors follow the laws of perfect gases.

The experimental results given in Table I were plotted on a large scale to give the usual pressure-temperature curves. Curves were drawn for each acid composition and for the total and partial pressures. These curves were then carefully smoothed out so as to be consistent. From these smoothed curves the plot, Fig. 2, was constructed. On the original large scale plot, 1 mm. =  $\frac{1}{20}$  inch. The smoothed values

read graphically from this large scale plot are assembled in Table II, where the results are recorded to the nearest half millimeter,—no further significant figures being warranted by the precision of the experimental data and methods of calculation. The values in Table II and Fig. 2 are satisfactory for all technical calculations involved in acid manufacture.

Other measurements of the vapor pressures of nitric acid solutions have been made by Saposhnikoff,<sup>3</sup> Burdick and Freed,<sup>4</sup> and Creighton and Githens.<sup>5</sup> Saposhnikoff made his measurements at 15° on concen-

trations of nitric acid ranging from 65 to 100%. Decomposition of nitric acid vapor into nitrogen oxides was encountered at the higher concentrations. Saposhnikoff used a dynamic experimental method and fails to give the method of computation of his results.

Burdick and Freed's measurements were also made by the dynamic method, and cover the range 24 to 70% acid at three temperatures, 25°, 50°, and 75°. Their results agree very well with those disclosed in this article. Below are compared the data of the two investigations for acid concentrations employed by both and at 50°.

% $\text{HNO}_3$ (S.-T.) (B.-F.)		Partial Pressure $\text{H}_2\text{O}$ (S.-T.) (B.-F.)		Partial Pressure $\text{HNO}_3$ (S.-T.) (B.-F.)		Total Pressure (S.-T.) (B.-F.)

Creighton and Githens measured total vapor pressures by a static method. They determined the boiling temperatures under reduced pressures down to 75°. Their results are considerably higher than ours at corresponding temperatures and concentrations.

Kaltenbach<sup>6</sup> gives graphically the boiling points of nitric acid solutions at atmospheric pressure and the composition of the vapors in equilibrium with the boiling solutions. His results for the partial pressures of nitric acid vapor appear to be lower for concentrations below the acid of maximum boiling point and higher for those above than extrapolation of our results would indicate.

### Summary.

1. The total and partial vapor pressures of nitric acid solutions of concentrations approximately 20, 40, 56, 68, and 80% by weight at temperatures of 0°, 35°, 50°, 65°, and 80° have been measured.

2. From these data vapor pressures for each 10% increase in concentration and 10° rise in temperature have been calculated by graphic methods.

3. Attempts to measure the vapor pressure of 90% nitric acid were unsuccessful owing to decomposition of the acid at all the experimental temperatures except at 0°.

The authors wish to acknowledge the helpful advice of Mr. Roger Williams during the course of the investigation and the assistance of Mr. F. C. Blake in constructing the curves.

## A HIGH PRESSURE DUE TO ADSORPTION, AND THE DENSITY AND VOLUME RELATIONS OF CHARCOAL.<sup>1</sup>

(Papers on Surface Energy and Surface Forces.)

BY WILLIAM D. HARKINS AND D. T. EWING.

Received May 2, 1921.

### 1. The Compression of Liquids by Charcoal.

While working on Problem 108 of the National Research Council in the year 1918 the writers discovered an interesting relationship, which is that the volume of different liquids adsorbed by the same charcoal

<sup>6</sup> Kaltenbach, *Chimie Ind.*, 2, 143 (1919).

<sup>1</sup> Presented at the Philadelphia meeting of the American Chemical Society, September 1919. This problem was suggested to the National Research Council by the senior author. The data for one charcoal with 11 liquids were published in February 1920 (Harkins and Ewing, *Proc. Nat. Acad. Sciences*, 6, 49-56 (1920)). The present paper is an abstract of a thesis presented to the University of Chicago in August 1919 by D. T. Ewing, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

increases in the same order as the percentage compression for a definite high pressure,—such as twelve thousand atmospheres. Thus the charcoal seems to produce the same change in the volumes of liquids which penetrate it, as is given by a high pressure. In our preliminary report it was stated that while accurate calculations of the pressures which would have to be put upon these liquids to give the same percentage compressions, could not be made in the absence of data on an incompressible or very slightly compressible liquid, it seemed likely that the order of magnitude might be represented by twenty thousand atmospheres<sup>2</sup> in excess of the internal pressure of the liquid. While there is nothing novel in the idea of the existence of such powerful adhesional forces at the surface of a solid, their experimental demonstration in such a direct way is somewhat remarkable, since the highest values for the internal pressures of liquids thus far experimentally demonstrated<sup>3</sup> are 34 atmospheres with water at 24.4°, 39.5 atmospheres for ethyl alcohol at 22.5°, and 72 atmospheres for ether at 17.7°.

Our hypothesis that the compression of the liquid is due to a pressure of this order of magnitude at the interface liquid-charcoal, is supported by the very interesting work of Lamb and Coolidge,<sup>4</sup> who approach the subject from an entirely different experimental standpoint. They find that the net heats of adsorption are closely proportional to the heats of compression under high pressure, which “indicates that the liquids are all attracted by the charcoal with substantially the same force, and that the net heat of adsorption is merely a heat of compression. The absolute value of this attractive force appears to be about 37,000 atmospheres when 1 cc. of liquid is adsorbed on 10 g. of charcoal.” Still another paper,<sup>5</sup> also published later than our own, comes to the conclusion that the volume of a liquid in charcoal is different from the volume of the same mass of the same liquid in bulk.

<sup>2</sup> It is obvious that the magnitude of the mean pressure decreases as the volume of liquid considered increases.

<sup>3</sup> Donny, *Ann. chim. phys.*, 16, 167 (1846); Berthelot, *ibid.*, [3] 30, 232 (1850); Moser, *Ann. phys.*, [2] 160, 138 (1877); Helmholtz, *Ges. Abh.*, 3, 264 (1887); Worthington, *Phil. Trans.*, [A] 183, 355 (1892); Meyer, “Zur Kenntnis des negativen Druckes in Flüssigkeiten,” Halle, 1911. The heat of adsorption was discovered as a phenomenon by Pouillet nearly one hundred years ago (*Gilb. Ann.*, 73, 356 (1823)). The hypothesis that the high heat of adsorption indicates that it may be convenient to look upon adsorbed material as in a compressed state, is also very old. It is discussed in Freundlich’s “*Kapillarchemie*” (Leipzig, 1909, p. 111). However the work of the present writers gives the first direct experimental demonstration of this compression, and shows that the magnitude of the effect is much greater than has usually been supposed.

<sup>5</sup> A. M. Williams, *Proc. Roy. Soc. (London)*, 98A, 223–34, December (1920). The writer has not been able to consult this paper since this number has failed to reach any of the Chicago libraries.

In March 1920 Cude and Hulett<sup>6</sup> published data on the volume and density relations of one charcoal as obtained with four different liquids. It happened that at the time our preliminary paper giving data on 11 different liquids had been published, and we were somewhat disturbed to find that the agreement between the two sets of data was not as perfect as might have been desired, though the only discrepancy was for the single liquid benzene. However, on this account the publication of the present paper has been delayed for considerably more than a year. During this time Mr. C. E. Monroe has repeated a number of the determinations and has extended the investigation to other liquids for which the compressibilities have been determined by Bridgman. His results will be published in a separate paper, but it may be stated that they agree almost exactly with those of the present and also of the preliminary publication.

In the experiments presented here the charcoal was outgassed by the use of a mercury condensation pump with a large throat and connecting tube (25 mm. in diameter), but it was found necessary to constrict the tubes near the charcoal bulb to 1 cm. The apparatus first used was similar to that described by Lemon<sup>7</sup> since we had two sets of this apparatus for work on the speed of adsorption of various poison gases. However such an elaborate apparatus is unnecessary for the work on liquids, and a system without stopcocks was found to be better for this purpose. The outgassing was first conducted at low temperatures, with a gradually increase to 600°. The tubes of charcoal were kept at the latter temperature from two to three days, or until the pressure registered by the McLeod gage had fallen to 0.0001 mm. and had remained as low as this for at least 6 hours. This pressure was determined while the pump was still running, but the tubes of charcoal were connected to the main vacuum line (1.5 cm. in diameter) between the gage and the pump. The neck of the bulb, which usually contained about 10 g. of charcoal, was then sealed off to a point while the bulb was still kept hot in the electric furnace. The bulb was cooled, the point dipped under the surface of the hot liquid, and broken off, so as to allow the liquid to rise into the tube. The tube was weighed at intervals, being kept in a thermostat at 20.00° except during the periods it was kept in the balance. The surface of the liquid was so adjusted in the thermostat that the lower part of the meniscus was exactly at a fine circular graduation made on the neck of the tube where it had been constricted to a capillary. After the drift had ceased, the final data as recorded, were obtained. The character of this drift has been treated by Cude and Hulett, and will be considered by Mr. Monroe, so only the final density data will be presented here.

<sup>6</sup> Cude and Hulett, *THIS JOURNAL*, 42, 391-401 (1920). Their results on benzene are affected by some factor which we have not been able to duplicate.

<sup>7</sup> Lemon, *Phys. Rev.*, 14, 283 (1919).

## 2. Apparent Density and Volume Relations of Charcoal.

The most closely agreeing data were obtained by the use of a steam activated, coconut-shell, gas-mask charcoal E 602, which gave a service time of 47.2 minutes by the accelerated chloropicrin test. On account of the close agreement of the three or more density determinations with each liquid, in general to  $\pm 0.001$ , only the average values will be included in Table I, which gives the results for this charcoal. The density listed in Col. 2, and the pore volume given in Col. 3, are not the real, but only the apparent values, calculated on the basis that the liquids are incompressible, or what amounts to the same thing in this case, that the liquids are not attracted by the charcoal sufficiently to cause any compression. Since apparently this kind of assumption is not justified, the true density and pore volume can be calculated only when the correct interpretation of the cause of the considerable variation shown in the table, is obtained.

TABLE I.

APPARENT DENSITY AND PORE-VOLUME DETERMINATIONS FOR A STEAM-ACTIVATED COCONUT-SHELL GAS-MASK CHARCOAL.

(Charcoal E 602; service time 47.2 minutes;  $-\Delta v = 0.058$  cc.)

(Data at 25°.)

1. Liquid.	2. Apparent density.	3. Pore volume 1 cc.	4. Percent compressed 12000 at- mospheres. <sup>a</sup>	5. Surface tension, dynes per cm. $\gamma$ .	6. Viscosity in absolute units. $\eta$ .	7. $\frac{\gamma}{\eta}$ .	8. $\frac{b}{\eta} \times 10^4$ .
Mercury .....	0.865	.....	.....	57.0	.....	.....	..
Water .....	1.843	0.534	20.51	72.8	0.0101	7200	14
Propyl alcohol .....	1.960	0.559	22.93	23.7	0.0223	1062	76
Chloroform .....	1.992	0.566	.....	27.13	0.0057	4760	45
Benzene .....	2.008	0.568	.....	28.88	0.0064	4510	54
p-Xylene .....	2.018	0.571	.....	28.33	0.0064	4430	81

Carbon disulfide .....	2.057	0.580	25.75	31.38	0.0037	8480	34
Acetone .....	2.112	0.590	27.0	23.50	0.0033	7120	44
Ether .....	2.120	0.592	30.0	17.1	0.0024	7125	39
Pentane .....	2.129	0.593	More than ether	About 15	0.0024	6200	65

<sup>a</sup> The solubility of gases in these liquids increases in *general* with the percentage of compression or the compressibility, but the order is not exactly the same. The values for the density and for the pore volume listed in this table are calculated on the basis of the incorrect assumption that the liquids are incompressible. The same values would be obtained if the liquids are compressible but are not compressed. The eighth column gives the values of  $b$  of van der Waals' equation.

In order to understand the volume and density relations upon which the adsorptive properties of charcoal depend, it is important to obtain an idea of the structural relations of coconut charcoal, insofar as the latter can be revealed by the use of the microscope. The writers have about 60 microphotographs, with magnifications as high as 2000, prepared by Dr. Rheinhardt Thiessen of the U. S. Bureau of Mines, and these have been used in the present study of the pore volume relations. Unfortunately none of these can be presented here, but reference may be made to three microphotographs reproduced in an earlier paper by Lamb, Wilson, and Chaney,<sup>8</sup> which do not, however, represent all of the types of structure found. A reference to their Figs. 7 and 8 (pp. 428 and 429) of their paper will show that the lumps of charcoal contain many pores which are visible at a magnification of 732 diameters. Those visible at a magnification of 2000 may be called capillaries or macropores. The walls of carbon, which are represented by the light portions of the figure, are undoubtedly very porous, and contain an enormous number of "micropores" which are ultramicroscopic. A study of the photographs shows that the mean diameter of the macropores is about 12 microns.<sup>9</sup> The micropores may be defined arbitrarily as those whose diameters are less than  $10^{-5}$  cm. (less than 100 millimicrons), though vapor-pressure measurements indicate, insofar as they are of any value for this purpose, that they are mostly of the order of  $10^{-6}$  cm. or less, in diameter.

Since mercury penetrates neither the capillaries nor the micropores, the density given in Tables I and II, with this liquid used to fill the "voids" between the lumps of charcoal, is that of the lumps themselves, walls, micropores, and capillaries included, or what is known as the lump or "block density." It will be seen that this density is close to 0.85 for two of the highly activated coconut-shell charcoals, but is considerably higher for the slightly activated charcoal E 621, for which the value is practically 1.000. The density of the cedar wood charcoal, 0.815, is very nearly the same, yet this specimen shows an almost zero service time, while beechwood charcoal, also a very poor adsorbent, has a block density of only 0.521. The active carbon 4, with a moderately high service time of 40.9 minutes, has a moderately low density (0.709), and the much

<sup>9</sup> This diameter is dependent upon the methods of production of the charcoal.

less active No. 1, also made from anthracite coal and pitch, has a much higher density (1.175), while the still less active carbon No. 3, with the low service time of 11 minutes, has a very high density (1.490).<sup>10</sup>

### 3. Relation of the Total Apparent Pore Volume to the Compressibility of the Liquids.

The most remarkable feature of Tables I and II is that the apparent density and total pore (capillary and micropore) volume depend upon the liquid in which the charcoal is immersed, and in general both increase markedly either as the compressibility increases or the viscosity decreases. This suggests alternative hypotheses, which lead to practically opposite conclusions with respect to the density. The first of these, supported also by the later data obtained by Mr. Monroe, is that *the liquid in the micropores is very highly compressed by adsorption, and that this compression is greater, the greater the compressibility of the liquid in bulk.*<sup>11</sup> That the molecules of the liquid should be drawn closer to the atoms in the surface layers and edges, seems to be the normal supposition when the magnitudes of the adhesional forces are taken into account, since such forces are much more intense than those which hold the molecules of liquid together. While this may not have been proved directly, it is evident that the energy of adsorption for a charcoal surface is very much higher than the energy of cohesion in water or in an organic liquid, since the energy of vaporization of such an adsorbed liquid is very much greater than that of the liquid itself. In addition to this the work of this laboratory has shown that even on a mercury surface the energy of adhesion for these liquids is usually three or more times that in the pure liquids. It should be noted that this factor is altogether too low to express the relations at a carbon surface.

However, the compressive effect need not vary directly as the compressibility of the liquid in bulk, since the liquid is not compressed isotropically. A second factor which might be expected to cause a divergence is that the force of adhesion is not the same for all of the liquids. When these factors are considered, the agreement in the order seems very remarkable.<sup>12</sup>

When the highly evacuated lump of charcoal is put under the surface of a liquid, the latter enters the capillaries or macropores, and these in the charcoals which preserve to a considerable extent the original structure of the shell, have diameters of the order of 0.012 mm. in diameter, so they are filled quickly, provided they are in direct communication with the

<sup>10</sup> All of these data refer to the lump density.

<sup>11</sup> The second hypothesis suggested, that the most viscous liquids penetrate least, does not seem to be in good agreement with the experimental data, as indicated later in the text.

<sup>12</sup> This indicates that the variation of the adhesive force with a change from water to various organic liquids, is not very great. This agrees with the conclusion of Lamb and Coolidge (Ref. 4).

liquid, but the micropores are filled much more slowly. In the capillaries the driving force of penetration is the surface tension, while the retarding force is the viscosity, and the speed of penetration should vary as the ratio  $\gamma/\eta$  where  $\gamma$  represents the surface tension and  $\eta$  the viscosity. That this is true has recently been shown by Washburn. It might be thought that the differences in the volumes of the liquids which penetrate the charcoal are due to incomplete penetration by some of the liquids, especially in the cases of water and propyl alcohol, but there is *no parallelism* between the values of the ratio  $(\gamma/\eta)^{1/2}$  and the volume of liquid which penetrates. However, as the pores become finer the influence of the viscosity may become predominant, especially when the liquid after passing through a part of a narrow pore enters into a region where its cross section becomes enlarged.

While a consideration of the relation between the pore volumes and the viscosities of the liquids as presented in Table I, shows that the data would in general support the idea that the effects might be due to different penetrations of the charcoal by the different liquids, the least viscous penetrating most, it will be seen that the propyl alcohol is very badly out of order in this sense, though in exactly the order prescribed by the compressibility hypothesis. Since several other liquids have been found by Mr. Monroe which are also out of order with respect to viscosity, but in the order of the compressions, it seems evident that at least the greater part of the observed differences in volume is due to the compression of the liquid, though the viscosity may exert a minor influence upon them.

The apparent densities in water of the coconut-shell charcoals as given above are 1.843 and 1.863; that of the similar charcoal used by Titoff, 1.86; by Baerwald, 1.92; and by Miss Homfray, 1.66; by Cude and Hulett, 1.854 on 18- to 20-mesh, and 1.900 for the same charcoal of 100- to 200-mesh (per inch). Kerosene gave very nearly the same apparent density with charcoal E 602 as benzene, or about 2.008. With this may be compared the data obtained by Chaney and Apmann, who determined the apparent density in kerosene of 30 charcoals, and found that the lower the value of this quantity, the lower in general is the service time. Thus densities in kerosene of 2.14, 2.17, 2.11, 2.11, 2.08, 2.02 and 2.02, correspond respectively to service times of 68, 64, 60, 59, 57, 55, and 54 minutes; while at the other extreme, densities of 1.98, 1.86, 1.87, 1.66, 1.63, and 1.66, correspond to service times of 33.1, 30.7, 27.6, 17.8, 8.0, and 4.3 minutes. Their data are in good agreement with the value found here, since a density of 2.02 in kerosene, the value corresponding to Table I, was found by them to correspond to a service time of 41 to about 49 minutes, which is not very far from that given in Table I.

However, there is not such good agreement with the data obtained by Cude and Hulett,<sup>6</sup> as is shown in Table III.

TABLE III.

APPARENT DENSITIES OF TWO SPECIMENS OF COCONUT-SHELL CHARCOAL.

Liquid.	Cude and Hulett charcoal A 909 (18- to 20-mesh).	This investigation charcoal E 602 (10- to 14-mesh).
Water .....	1.854	1.843
Benzene .....	1.797	2.008
Carbon disulfide.....	1.915	2.057

The discrepancy in the sign of the difference exists only in the single case of benzene. This liquid exhibited the same relative order in our investigations of two other charcoals, A and No. 1, so its position in the series can hardly be an accident, especially as many determinations were run for charcoal E 602. Some factor was evidently present in the work of Cude and Hulett,<sup>6</sup> which was absent in our own. It is possible that the discrepancy is due to the extent of the outgassing, which was more thorough in our work, since we happened to have a very much more rapid vacuum pump, used a large connecting tube in place of their capillary, and outgassed for 3 days.

It is of interest to note that in the more active charcoals the apparent volume of ethyl ether, minus the volume of water, in the pores of 1 cc. of charcoal ( $-\Delta v$ ),—which shows how much more the ether is compressed than the water,—is nearly constant and about 0.055 cc. as is shown by Table IV.

TABLE IV.

COMPRESSION OF ETHER IN CUBIC CENTIMETERS PER CUBIC CENTIMETER OF CHARCOAL, MINUS THE COMPRESSION OF WATER ( $-\Delta v$ ).

Charcoal.	Service time, minutes.	$-\Delta v$ .
E 602 .....	47.2	0.058
Rankinite A .....	42.9	0.052
Active carbon 4 .....	40.9	0.067
Charcoal 1 .....	32.0	0.053
E 621 .....	27.0	0.051
Active carbon 1 .....	19 0	0.043
Active carbon 3 .....	1.10	0.018
Cedar wood charcoal .....	0.0	0.008
Beechwood charcoal .....	0.0	0.004

Of these charcoals the last, that made from beechwood, was the poorest adsorbent for chloropicrin as determined by the regular test. It is apparent that the value of  $-\Delta v$  is nearly constant as the service time decreases from 47 to 27 minutes, but falls very rapidly as the service time decreases to 19 and 11 minutes, while the charcoals which give practically a zero service time, give also a very small value for the compression decrement ( $-\Delta v$ ).

#### 4. The Heat of Adsorption of Liquids in Charcoal.

When lumps of outgassed charcoal are dropped into a liquid, or when a liquid is poured into a tube which already contains the charcoal, the liquid

penetrates the charcoal, with the result that the carbon surface of the pores disappears, and a carbon-liquid interface takes its place. In this process heat is developed, and this may be specified as the heat of immersion, of adsorption ( $-Q_a$ ), or of absorption. Thus 1 g. of bone charcoal, which had not been outgassed, gave off 18.5 calories when immersed in water, while the same weight of fuller's earth in the same liquid, gave 32 calories. The data of Lamb and Coolidge on the heat of adsorption of vapors by charcoal, indicate that the heat of immersion of a typical coconut-shell charcoal in carbon disulfide is of the order of 35 calories per gram.

The heat of immersion of a solid whose surface is so nearly plane that its surface energy is essentially equal to that of the same area of a plane surface of the same material, or the heat of adsorption of a liquid on the surface of the solid, may be defined in a corresponding way as the amount of heat liberated ( $-Q_a$ ) when a solid with a surface of this type, and of an area of 1 sq. cm. is immersed in a liquid in such a way as not to increase materially the area of the surface of the liquid. In this process the surface of the solid would disappear, and in its place would appear the same area of interface solid-liquid. The heat liberated ( $-Q_a$ ), would be equal to the total amount of energy given off in the process when carried out isothermally ( $E_a$ ), and this is equal to the total surface energy of the solid ( $E_s$ ), minus the total surface energy of the interface ( $E_i$ ), for 1 sq. cm. of surface. Since the total surface energy is always equal to the free surface energy ( $\gamma$ ) plus the latent heat of the surface ( $-T \frac{\partial \gamma}{\partial T} = l$ ), the following equation expresses the value of the heat of adsorption.

$$-Q_a = E_a = E_s - E_i = \gamma_s + l_s - (\gamma_i + l_i) = \gamma_s - T \frac{\partial \gamma_s}{\partial T} - \gamma_i + T \frac{\partial \gamma_i}{\partial T} \quad (1)$$

It is obvious that this equation is also valid for the heat of immersion of a liquid, or for the heat of adsorption of one liquid on the surface of another liquid, so in its more general sense the subscript *s* refers to the phase whose surface is already developed, but later disappears, giving place to an interface of the same area. The heat liberated on the immersion of a solid has always been found to be a positive quantity, which indicates that the total interfacial energy per unit area is always less, so long as this holds true, than the total surface energy of the solid. That this is not always the correct sign of the effect, at least when only liquids are involved, is shown by the fact that hexane, octane, and carbon tetrachloride have negative heats of immersion in water equal respectively to  $-0.21$ ,  $-0.21$ ,  $-0.26$ , times  $10^{-6}$  calories per sq. cm. at  $20^\circ$ , though the heats of immersion of water in these liquids are all positive,  $1.4$ ,  $1.34$ , and  $1.05$  times  $10^{-6}$  calories per sq. cm. Even in the case of two liquids heat is almost always evolved on immersion as the result of the surface energy changes. Thus, for example, the heat of immersion of normal octyl

alcohol at 20° in water is 1.28, and of water in octyl alcohol, 2.85, in terms of the units used above.

The heat liberated on adhesion ( $-Q_A$ ), and the total adhesional energy ( $E_A$ ), are always larger positive (or smaller negative) quantities than those which give the heat liberated on immersion (heat of adsorption), provided the surfaces are plane. The following equation gives the heat of adhesion.

$$-Q_A = E_A = E_s + E_l - E_i = (\gamma_s + l_s) + (\gamma_l + l_l) - (\gamma_i + l_i) \quad (2)$$

These are the same as the heat and energy of approach, since the surfaces of two phases already in existence, approach each other and disappear, while an interface, equal in area to that of either surface which disappears, takes their place. The heat of adhesion is 2.6 for water-hexane, 4.0 for water-octyl alcohol, 2.5 for water-carbon tetrachloride, all in  $10^{-6}$  calories per sq. cm. at 20°.

When a liquid spreads over a solid, the surface of the solid disappears, while an interface of the same area appears. If the solid has a plane surface, then a liquid surface of the same area also appears; so, provided the liquid layer is not too thin, the following equation holds

$$-Q_{sp} = E_{sp} = E_s - (E_l + E_i) = \gamma_s + l_s - (\gamma_l + l_l) - (\gamma_i + l_i) = E_A - E_c$$

where  $E_c$  represents the energy of surface cohesion of the liquid.

Obviously

$$-Q_a = E_a = E_A - E_l$$

or the heat liberated by the adsorption of a liquid equals the energy of adhesion minus the surface energy of the liquid. Also

$$-Q_a = E_a = E_{sp} + E_l.$$

and

$$E_{sp} = E_A - 2E_l.$$

The heat of adsorption of a saturated vapor is

$$-Q_g = (\gamma_s + l_s) - (\gamma_i + l_i) + \lambda v = E_s - E_i + \lambda v$$

where  $-Q_g$  is the heat of adsorption of enough vapor to form a liquid in bulk covering the solid surface at constant temperature, and  $\lambda$  is the latent heat absorbed in the vaporization of the liquid per unit volume of vapor. It is assumed here that the area of the surface of the liquid formed is negligible in comparison with the area of the interface which is formed.

While we do not have the values of the above quantities for carbon, they have been determined in this laboratory for the interfaces between mercury and other liquids; in which case the values for the liquid mercury may be substituted for the values for the solid in the above equations. The heat of adsorption as defined above is thus found to be 3.25 for *iso*-butyl alcohol, 2.60 for *secondary* octyl alcohol, and 3.13 for octane, all

in  $10^{-6}$  calories per sq. cm. The heat of spreading of *n*-octyl alcohol on water is about that of *iso*-butyl alcohol on mercury, but that for octane on water is less than half the similar value for mercury.

### 5. The Area of the Surface Exposed to a Liquid inside One Gram of Charcoal.

That there is anything in a lump of charcoal which corresponds to a plane surface is altogether improbable; and it is not unlikely that what corresponds to a surface may be molecularly rough, so that it would be impossible to designate any number which would correspond to the area in square centimeters of the surface. However, several estimates of this surface area have been made. Thus Lamb, Wilson, and Chaney<sup>8</sup> have estimated the surface in 1 g. of an activated charcoal as 1000 square meters, Lowry and Hulett<sup>13</sup> obtain the value 200 square meters for a similar charcoal, while A. M. Williams,<sup>14</sup> in developing a new interpolation formula for the adsorption of gases, calculated the surface of the non-activated charcoal used by Miss Homfray as 131 square meters.

The data given in the preceding section of this paper, together with the equations given there suggest an independent method of determining whether these estimates are of the right order of magnitude to represent what may be called the "apparent surface," which will be defined as the area of the plane surface of the same material which will give the same heat of immersion or of wetting when wet by the same liquid in bulk. Unfortunately for our purpose the heat of adsorption of charcoal has been determined in none of the liquids given there, so what will be presented here will be merely illustrative of the method. We will suppose that the heat of immersion of charcoal in carbon disulfide is as large or larger than the heat of immersion of mercury in octane, which does not seem unreasonable. If we assume that these two heats of immersion or of wetting are equal, the heat of immersion of one gram of charcoal in carbon disulfide, 35 calories, would correspond to an *apparent area* as defined above of about 120 square meters. Since it is practically certain that the heats of immersion of carbon are higher than those for mercury, this result would seem to represent a maximum which is still too large. The method of calculating the area of the charcoal surface by the use of the capillary equation of Anderson<sup>15</sup> cannot be expected to give any real correspondence with even such an apparent area, since his equation obviously breaks down completely at the diameters of the micropores which are calculated from the equation. Thus Lowry and Hulett<sup>13</sup> by using his equation find  $1.6 \times 10^{-8}$  cm. as the minimum, and  $8.3 \times 10^{-7}$  cm. as the maximum diame-

<sup>13</sup> Lowry and Hulett, *THIS JOURNAL*, **42**, 1393-1419 (1920).

<sup>14</sup> A. M. Williams, *Proc. Roy. Soc. Edinburgh*, **39**, 48-55 (1918).

<sup>15</sup> Anderson, *Z. physik. Chem.*, **88**, 191 (1914).

ters of the pores in all of the charcoals investigated by them; and calculations from data obtained in this laboratory give values of the same order but without the above minimum. These dimensions are of such a small magnitude as to approach so closely molecular dimensions, that an equation such as the one cited, developed from the relations in a capillary tube of ordinary dimensions is altogether without meaning. However, if the lower limits for the diameter at which it is still valid could be determined, it would be useful in calculating how much of the liquid is contained in pores of that and smaller diameters. Experimental work of the heat of immersion of porous solids in liquids was begun in this laboratory several years ago, but was interrupted. It will be resumed in the coming summer.

## 6. Volume of the Pores, and the Density of Charcoal.

If either charcoal E 602 or No. 1, for which the data are very nearly identical, is taken as a characteristic coconut-shell charcoal, it may be easily seen that if the liquids are compressed by the charcoal, the total pore volume is less than even the volume of the least compressible liquid which enters the pores, when the latter is measured before the penetration occurs, as was done in the experiments. Thus the total pore volume for E 602 is less than 0.534 cc. per cc., and in the case of No. 1 it is less than 0.533. Since the macropores have diameters of the order of  $1.2 \times 10^{-3}$  cm., it is evident that in them the liquids are not materially compressed, so practically the whole of the compression occurs in the micropores.

Experiments upon the adsorption of benzene show that these charcoals adsorb about 0.39 cc. of liquid benzene, 0.35 cc. of water, 0.41 cc. of ether, etc., as measured before adsorption. From this result, together with the data on the adsorption of liquids it may be calculated that the volume relations for these charcoals are approximately 0.54, 0.28 and 0.18 for the volume of carbon (volume not occupied by liquid), volume of micropores, and volume of macropores, respectively.

These values give a density of 1.60 for the active charcoal. It may be noted that the two specimens of wood charcoal which showed almost no compressive action on the liquids, those from beech and cedar wood, had densities equal to 1.65 and 1.50 respectively, or not far from the estimated value for the carbon in the coconut-shell charcoal.

While Table I does not give any values for liquids whose percentage compressions have been determined directly at 12,000 atmospheres as lying between that of propyl alcohol and that of carbon disulfide, the determinations on the compressibility of liquids at lower pressures indicate that chloroform, benzene, and *p*-xylene are in the proper order. Mr. Monroe's paper will remedy the apparent deficiency, since he has determined the pore volumes for 5 liquids which lie in this range; amyl alcohol, isobutyl

alcohol, ethyl iodide, and ethyl and methyl alcohols. His results give extremely strong additional evidence in favor of the compression hypothesis here presented.

## 7. The Small Effects of the Size of the Molecules, and of Unequal Adhesional Attractions.

Calculations made on the relation between the lowering of the vapor pressure produced by charcoal and the size of the micropores indicate such small dimensions for the latter as to suggest that the size of the molecules might be an important factor in determining the amount of liquid which will enter them. This idea occurred to the writers early in the work, and was suggested to them repeatedly by others. However, although a number of liquids were chosen with the purpose of varying the molecular size considerably, this effect is not so large that it has been possible to detect it as yet. In this connection a determination of the pore volume was made with mesitylene, a liquid whose molecules are very large. For the liquids used the values of  $b$  of the van der Waals' equation varied from  $14 \times 10^{-4}$  for water to  $88 \times 10^{-4}$  for mesitylene, which indicates a considerable variation in molecular size. Also it would seem that the force of compression might vary with the nature of the adsorbed liquid, which would indicate that the percentage compressions considered should not be taken at a fixed pressure as was done in Table I. It is evident from the data published here, and even more so from other data to be published later, that these two effects considered in this paragraph are so small as to be obscured by the compression itself.

## Summary.

1. This paper gives evidence in favor of the hypothesis proposed earlier by the writers, which is that *the liquids which penetrate into charcoal are compressed by the action of a force, due to molecular attraction, which acts as a pressure of many thousand atmospheres*. In the earlier paper it was estimated that the pressure corresponded to twenty thousand atmospheres or more. The present paper indicates that it is the liquid in the micropores and not in the macropores which is compressed. On this basis the pressure would probably be considerably higher than the previous estimate, since at that time only the total pore volume was known and considered. Not only charcoal, but also all other porous substances, such as porous ceramic materials, and also very fine powders, should exert this compressive effect, but in general to a much smaller extent. The remarkable feature of the experiments listed is that they demonstrate the compression by direct measurements of the volume changes in the liquids. Experiments on the internal pressure of liquids have not succeeded in demonstrating pressures higher than 72 atmospheres.

2. Ether, which is much more compressible than water, occupies a volume in the charcoal which is about 10% less than that occupied by the amount of water which is, outside the charcoal, equal in volume to the ether. It seems probable that the water in the micropores is compressed by about 25%, or even more, while the ether is compressed by about 40%. It is evident that the liquids in the macropores, of the order of  $1.2 \times 10^{-3}$  cm. in diameter, are not compressed sufficiently to produce any noticeable effect upon the volume.

3. The true volume relations in 1 cc. of a characteristic coconut-shell charcoal may be estimated as: volume of micropores, 0.28 cc.; of macropores, 0.18 cc.; of carbon, 0.54; which gives a density of about 1.60 for the carbon. The density of the lumps of such a charcoal is about 0.868, though this lump or "block" density is as high as 1.49 for a charcoal made from anthracite coal, and as low as 0.52 for a wood charcoal.

4. The charcoals which are inactive as adsorbents of gases do not exert a compressive effect upon the adsorbed liquids of a sufficiently great magnitude to be very evident, though there seems to be a slight effect of this nature.

5. The densities of the carbon in the two inactive wood charcoals investigated are 1.65 and 1.50, which is not very far from the estimated density for the carbon of the active charcoals. It is evident that charcoals from which the hydrocarbons have been imperfectly eliminated, may have much lower densities still.

6. When coconut-shell charcoals alone are considered it is found that in agreement with the data obtained by Chaney and Apmann, the lower the apparent density in an organic liquid, the less is the adsorptive action on vapors. The present investigation indicates that this relation may be expected to hold the better the more compressible the liquid which is absorbed, so either ether or pentane or another highly compressible liquid should be used in such tests.

7. Simple thermodynamic equations are given for the heat of immersion or adsorption of a plane surface. While there is probably no definite area of surface inside a lump of charcoal, a definition for an "apparent area" may be given. The one chosen here is that the "apparent area with respect to the heat of immersion" is the area of the plane surface of carbon which will develop the same amount of heat on immersion as is equal to that developed by the immersion of 1 g. (or 1 cc., if such a different unit is preferred) of the charcoal in the same liquid. Since the "film" in the charcoal is probably a number of molecules deep, this apparent area is probably larger than corresponds to the carbon surface. Nevertheless, this method of consideration gives rise to a lower estimate of the area than the others which have been given in the literature. Thus it is in-

licated that the apparent area defined in this way is less than 120 sq. meters per gram of charcoal.

8. The magnitude of the heat of immersion of liquids on mercury is  $3.13 \times 10^{-6}$  calories for octane and  $3.25 \times 10^{-6}$  calories per sq. cm. for *iso*-butyl alcohol.

The next two papers of this series will present additional data similar to those given here, and also on the amounts of different vapors adsorbed by the charcoals used in this investigation. These data will make it possible to calculate in much more detail the pressure and cohesional relations involved.

The writers wish to thank Mr. Chaney for preparing several special charcoals for use in this work, and to express their indebtedness to the Wolcott Gibbs Fund of the National Academy of Sciences for a grant which was used in the purchase of vacuum apparatus. While the grant was made for researches upon the cobalt ammines, the apparatus was diverted from this latter work during the war period.

The compressibility data used in this paper are those of Bridgman.<sup>16</sup> Without the results of his remarkable investigations at high pressures, the evidence in favor of the compression hypothesis developed by the writers would have been much less convincing.

Note added Oct. 26, 1921.

Washburn<sup>17</sup> has devised a method for determining the "true" volume of the pores in a ceramic material by the use of a gas, such as hydrogen or helium, as the fluid for filling the pores. This method has been tried in this laboratory, and has been found to be much less simple when applied to charcoal, but it will undoubtedly give consistent results when sufficient care is taken. The data obtained thus far will not be published until they are more carefully verified. With accurate data of this nature it may be possible to calculate more exactly the pore volume and the density of charcoal, though, on account of the small size of the molecules of helium the volume of the pores penetrated by this gas may be greater than that penetrated by the larger molecules of an organic liquid. Also it seems apparent that even at ordinary temperatures the density of the helium gas is not the same in the micropores as in the free gas, that is, there is a small amount of adsorption.

## THE SEPARATION OF THE ELEMENT CHLORINE INTO ISOTOPES (ISOTOPIC ELEMENTS).

### The Heavy Fraction from the Diffusion.

BY WILLIAM D. HARKINS AND ANSON HAYES.

Received May 2, 1921.

### Introduction.

This paper will describe the experimental work begun in the year 1915 in this laboratory for the purpose of demonstrating the correctness of the hypothesis advanced by Harkins and Wilson. This was that chlorine, magnesium, and silicon, as well as neon, are mixtures of isotopes.<sup>1</sup> That neon contains an isotope of atomic weight 22, had already been discovered by Thomson<sup>2</sup> by the use of the positive-ray method, but at the time when this investigation was begun it did not seem that its presence in neon had been demonstrated by sufficient experimental evidence to make its existence altogether a certainty.<sup>3</sup> It appeared important, therefore, to demonstrate the existence of isotopic forms of at least one of the *light* elements by making an actual separation of one of the above mentioned elements into at least two fractions which would differ in their atomic weights, as determined by some chemical method. The prediction of the existence of the isotopes of the specific light elements mentioned above, was made on the basis of their chemical or mean atomic weights, and at that time the atomic weight of silicon was not known with a high degree of precision, while the atomic weights of magnesium and of chlorine, especially the latter, were considered to be very exact. For this reason and also because the deviation of the atomic weight of chlorine from a whole number is the largest known for any light element, it was decided<sup>4</sup> to attempt the separation of chlorine into its isotopes.

Of the methods suitable for the separation of substances of almost identical chemical properties such as isotopes either diffusion or the use

<sup>2</sup> Thomson, "Positive Rays of Electricity," Longmans, Green and Co., London, 1913, pp. 114-5.

<sup>3</sup> A letter of the date May 5, 1915, from the Cambridge laboratory written by Dr. F. W. Aston, states "For my own part I am fairly confident of the existence of neon and meta-neon, but I do not consider the results so far warrant a definite statement to the public. It is a pity that several authors of text-books seem to have jumped to the conclusion that such has been made." In December 1919 Aston secured good evidence from the positive-ray method that Thomson's discovery was correct, and that meta-neon of atomic weight 22 exists.

<sup>4</sup> Harkins and Hall, *THIS JOURNAL*, 38, 53 (1916). The work was begun, however, by Harkins and Turner.

of a centrifugal machine seemed to give promise of the quickest attainment of results. Attempts were made to obtain funds for the construction of a centrifugal machine, since it seemed that a properly designed centrifuge might effect a comparatively rapid separation, but, since these attempts were unsuccessful, work was begun on a diffusion through the stems of church-warden pipes, as has been described by Harkins and Turner. A notice of the beginning of the experimental work was published in the year 1916.<sup>5</sup>

Not only was an apparatus constructed for the separation of chlorine, but Turner also built an apparatus containing about 12.2 meters of porous pipe stems, which was used in diffusing large quantities of hydrogen chloride. The diffusions were interrupted by the war, though a considerable amount of the latter gas was diffused by T. H. Liggett during the year 1917-8. In the autumn of 1919 the work was taken up by C. E. Broeker, who diffused fractionally both the light and heavy fractions. Preliminary analyses on the heavy fraction indicated that its atomic weight had been increased to 35.51, or by 0.05 unit, in February 1920, and a preliminary notice of the separation was published in the February, 1920, number of the *Physical Review*,<sup>6</sup> in *Science*,<sup>7</sup> and in *Nature*.<sup>8</sup> This seems to be the first separation of an element into isotopes, for which there is any satisfactory evidence, but attention should be called to the fact that Aston in 1913 made a preliminary report to the British Association on an attempt to separate neon into isotopes. Since he has not published the details of this work at any time, it is impossible to know what was accomplished, but Aston himself states that the results were not at all conclusive.<sup>9</sup> When the difficulties in purifying and handling neon,

<sup>5</sup> *THIS JOURNAL*, 38, 53 (1916).

<sup>6</sup> *Phys. Rev.*, 15, 74 (Feb. 1920).

<sup>7</sup> *Science*, N. S., 51, 289-91 (1920).

<sup>8</sup> *Nature*, 105, 230-1 (1920). A later note in *Nature*, Sept. 30, 1920, states that Brönsted and von Hevesy have succeeded in obtaining a difference of 1 part in twenty thousand in the density of mercury. This is less than one-thirtieth of the separation obtained earlier by Harkins and Broeker in the case of chlorine. A later paper in *THIS JOURNAL*, will show that Mulliken and Harkins have secured a separation of the isotopes of mercury more than twice as large as that reported by Brönsted.

<sup>9</sup> Aston, *Phil. Mag.*, 39, 450-51 (1920), states that in his early experiments he obtained a density difference of about 0.7, which would amount to 0.14 unit difference in atomic weight, provided no impurities were present. He states that his results were positive but not conclusive, and that in his later more elaborate apparatus he secured a density difference of only about 3/7 of the above amount, presumably because he used too great pressures in his apparatus. Aston's original report, *Report Brit. Assoc. Adv. Science*, 1913, p. 403, gave no details concerning this work. The higher value reported by Aston is altogether unreasonably large, if the theory of diffusion is taken into account, if the amount of neon produced was sufficient to be subjected to purification, since it would represent a cut of 470 thousand with a 100% efficiency. Thus even 10 liters of neon would give only 0.02 cc. While this amount might be increased by using

and the difficulty of detecting impurities, are compared with the relatively easy purification of hydrogen chloride, it will be seen that a difference of 0.05 in the atomic weight of chlorine is more conclusive than several tenths of a unit for neon, particularly when the neon is obtained, as in Aston's experiments, in very minute quantities.

In a recent note in *Nature* Aston<sup>10</sup> gives the impression that the separation of chlorine by ordinary diffusion methods is almost impossible, and considers that if we have obtained any separation it is very remarkable, since in the case of neon, where the separation is extremely difficult, only the 21st root is involved, while with chlorine it is necessary to "grapple with the 36th root." It should be pointed out that in considering only the roots involved Aston has come to a conclusion which is partly erroneous, since actually (see Table I) *a smaller cut is required to produce an increase of 0.05 in the atomic weight of chlorine than to produce the same increase in the atomic weight of neon.* Here the cut (C) is defined as the amount of the gas which passes into the diffusion tubes, divided by the amount of heavy fraction which is obtained after the diffusion. Thus, even apart from the great difficulty of securing a considerable quantity of pure neon, and the difficulties involved in keeping it pure, the theory indicates an additional disadvantage of neon for separations of this magnitude. However, as the deviation of the atomic weight increases the theory becomes more favorable to the neon, though the rarity of this gas and the other disadvantages mentioned above, together with the much smaller degree of precision in the determination of its atomic weight, more than counterbalance the advantages which arise.

The following table gives the values of the cut necessary to increase the atomic weight of chlorine and of neon by definite amounts, as calculated from the theory of Rayleigh, which relates to an ideal diffusion at low pressures into a vacuum.

TABLE I.

VALUES OF THE CUT  $(X + Y)/(x + y)$  NECESSARY FOR THE INCREASE OF THE ATOMIC WEIGHTS OF CHLORINE AND OF NEON BY DEFINITE AMOUNTS. A DIFFUSION OF THE HEAVY FRACTION. (Chlorine diffused as hydrogen chloride.)

(Percentage of isotope of atomic weight 37 in chlorine = 23, of atomic weight 22 in neon = 10.)

Increase of atomic weight.	Cut.	Chlorine. Corresponding enrichment.	Cut.	Neon. Corresponding enrichment.
0.05	160	1.1459	217	1.286
0.10	18,600	1.302	19,600	1.588
0.15	1,690,000	1.469	991,000	1.909
0.20	117,000,000	1.648	33,000,000	2.25

fractional diffusions it would seem practically impossible to secure the atomic weight change claimed upon enough material to allow of its proper purification with the amounts of neon at that time available.

<sup>10</sup> Aston, *Nature*, 105, 131 (1920).

Here  $x$  and  $y$  represent the number of mols of the light and heavy isotopes respectively in the heavy fraction after the diffusion, while  $X$  and  $Y$  represent the initial mol numbers. This table points out the important fact that it is easy to obtain an increase of 0.05 in the atomic weight of a *small quantity* of chlorine or of neon, and that it is also easy to obtain *very small quantities* of either with an increase of 0.10, provided the process is nearly 100% efficient in terms of the Rayleigh theory. However, if only very small quantities of the material are obtained, it is very difficult to make the thorough purifications which are necessary to give evidence that a separation has been effected. The table also shows that to attain an increase of 0.20 unit in the atomic weight, is very difficult, since to secure this by diffusing the heavy fraction in one operation would require that 130 tons of hydrogen chloride gas or 36 tons of neon be used provided one gram of product is to be obtained. While these amounts may be reduced considerably by the use of a system of fractional diffusions, this procedure, when used on gases, becomes very expensive either in terms of the original complications in the apparatus, or in the amount of labor necessary to keep a single system in operation.

In the above table the necessary enrichment ratio ( $r$ ) corresponding to the required change of atomic weight is equal to the value of  $(y/x)/(Y/X)$ . The equation of Rayleigh is

$$\frac{1}{C} = \frac{x+y}{X+Y} = \frac{X}{X+Y} r^{\frac{\mu}{\nu-\mu}} + \frac{Y}{X+Y} r^{\frac{\nu}{\nu-\mu}} \quad (1)$$

where  $\mu$  and  $\nu$  represent the diffusion coefficients of the light and heavy constituents respectively. This is easily converted into the form

$$\frac{Q}{Q_0} = \frac{1}{C} = r^{\frac{\mu}{\nu-\mu}} \left[ 1 + \frac{Y}{X+Y} (r-1) \right] \quad (2)$$

If it is assumed that the rates of diffusion of the gases vary inversely as the square roots of their molecular weights, this reduces to the following simple form.

$$\frac{1}{C} = r^{\frac{\sqrt{M_h}}{\sqrt{M_l}-\sqrt{M_h}}} \left[ 1 + h_0 (r-1) \right] \quad (3)$$

in which  $h_0$  represents the fraction of the heavy isotope  $Y/(X+Y)$  in the initial mixture, and  $M_l$  and  $M_h$  are the molecular weights of the light and heavy components of the mixture.

#### Relation between the Atomic Weights and Percentages of Two Isotopes and the Atomic Weight of the Mixture.

In order to calculate the cut necessary to produce a certain change in the atomic weight of a mixture of two isotopes, it is necessary to know

the fraction of each in the mixture, and this may be calculated from the mean atomic weight and the atomic weights of the pure isotopes. Let  $h_o$  and  $l_o$  represent the initial fractions of the heavy and light isotopes,  $h$  and  $l$  the similar values necessary to produce the required enrichment ( $r$ ), and  $M$ ,  $M_h$ , and  $M_l$ , the molecular weights of the mixture, of the heavy, and of the light fractions.

Then

$$l \cdot M_l + (1-l) M_h = M.$$

or

$$l = (M_h - M) / (M_h - M_l). \quad (4)$$

Similarly

$$(1-h) M_l + h M_h = M.$$

or

$$h = (M - M_l) / (M_h - M_l). \quad (5)$$

Divide (4) by (5):

$$r = \frac{h/l}{h_o/l_o} = \frac{M - M_l}{M_h - M} \cdot \frac{M_h - M_o}{M_o - M_l}. \quad (6)$$

By the use of Equations 3 and 6 the calculation of the cut necessary to produce any possible desired increase in atomic weight is very simple. It is obvious that the two equations may be combined into one.

$$\frac{Q_o}{Q} = \frac{1}{C} = \left[ \frac{M - M_l}{M_h - M} \cdot \frac{M_h - M_o}{M_o - M_l} \right] \frac{\sqrt{M_l} - \sqrt{M_h}}{\sqrt{M_l} - \sqrt{M_h}} \left[ 1 + h_o \left( \frac{M - M_l}{M_h - M} \cdot \frac{M_h - M_o}{M_o - M_l} - 1 \right) \right]. \quad (7)$$

If we let  $k$  represent  $\frac{\sqrt{M_h}}{\sqrt{M_l} - \sqrt{M_h}}$  the "diffusion exponent," then the diffusion equation reduces to the simple form:

$$\frac{1}{C} = [1 + h_o (r-1)] \times r^k. \quad (8)$$

The value of the diffusion exponent ( $k$ ) as thus defined is  $-37.503$  for the isotopic forms of hydrogen chloride provided the only isotopes have molecular weights 36.008 and 38.008, while for neon it has the value  $-21.488$ , provided the only isotopes have atomic weights 20 and 22. It may be noted that the values of the diffusion exponents are not very different from the mean molecular weights, but that this is not a general relation unless the isotopes differ in atomic weight by 2, is shown by the fact that the exponent for lithium, with atomic weight 6 and 7, is  $-13.48$ . The exponent for the isotopic forms of hydrogen bromide of molecular weights 80 and 82 (bromine of atomic weights 79 and 81) is  $-81.492$ . A convenient rule for keeping in mind the magnitude of the exponent is that it has a value equal to half a unit more than the mean of the molecular weights of the isotopes when the two molecular weights differ by 2. Thus for isotopes of atomic weights 223 and 225, the exponent is  $-224.5$ . Obviously the exponent has larger values when the difference between the iso-

topes is only 1, and smaller values when it is greater than 2. When the difference is 1 the exponent is equal to half a unit more than *twice* the mean of the atomic weights, and when it is 4, it is equal to half a unit more than *one-half* the mean.

Equation 8 may be put in the form

$$\frac{1}{C} = \left[ 1 + l_0 (r-1) \right] \times r^{k+1} \quad (9)$$

or

$$\frac{1}{C} = r^{\frac{\sqrt{M_l} - \sqrt{M_h}}{\sqrt{M_l} + \sqrt{M_h}}} \left[ 1 + l_0 (r-1) \right] = r^{k'} \left[ 1 + l_0 (r-1) \right]. \quad (10)$$

The numerical value of  $k'$  is always one unit less than that for  $k$ , and the mean of these two values is for two isotopes equal to the mean of the molecular weights when the molecular weight difference is 2, twice the mean of the molecular weights when this difference is 1, and one-half the mean of the molecular weights when this difference is 4, or

$$\frac{k + k'}{2} = \frac{M_l + M_h}{M_l - M_h} \quad (11)$$

and

$$k + k' = 1. \quad (12)$$

This relation becomes less exact as  $M_l + M_h$  becomes smaller, and as  $M_l - M_h$  becomes larger numerically. That it is sufficiently exact for accurate calculations is shown by the fact that the value of  $k$  calculated above (by the use of 7-place logarithms) in the case of hydrogen chloride is  $-37.503$ , while the value given by Equations 11 and 12, is  $-37.504$ .

In superficial discussions of the separation of isotopes there has been a tendency to concentrate the whole attention upon the diffusion exponent, and the effect of the initial percentages of the isotopes in the mixture has been neglected. That these percentages have a very marked effect upon the enrichment ( $r$ ) necessary to produce a certain change of atomic weight, is obvious. For example an infinite value of the enrichment ratio will serve to increase the atomic weight of lithium only from 6.94, the mean value, to 7.00, that for the heavier isotope so, for larger atomic weight differences for this element, the diffusions must be carried out upon the light fraction. In spite of the fact that the heavier isotope of this element has an atomic weight higher by 16.67% than that of the lighter isotope, a very high percentage difference, the theory does not indicate that the conditions for the separation are very favorable, since the enrichment ratio has a very large value. It is obvious that when a mixture of isotopes is divided into two equal parts by diffusion, the decrease of the mean atomic weight for the light fraction is equal to the increase for the heavy fraction. The equations for the light fraction are being worked out in this labora-

tory, and will not be discussed further here as they will be presented in a later paper to be published in *THIS JOURNAL* by Mulliken and Harkins. The relations have been tested by an experimental partial separation of mercury into two fractions, one of lower and one of a higher density than ordinary mercury. The most favorable proportion for the separation of a mixture of two isotopes is 50% of each. Thus, it has been found that a cut of 18,600 is necessary to increase the atomic weight of chlorine from 35.46 to 35.56, an increase of 0.1, in case hydrogen chloride is diffused. The percentage of heavy isotope in this ordinary chlorine is 23. Now it is quite remarkable that if the initial mixture contained 50% of each isotope, the same increase in atomic weight would be brought about with a cut less than  $\frac{1}{10}$  as great, or of 1,670.

Since the percentage of the heavy isotope in the heavy fraction of both chlorine and neon approaches more closely to 50% as the diffusion proceeds, the separation becomes more and more easy when considered in terms of the cut (though much more difficult in the sense that the amount of material available decreases rapidly.) Thus while the first  $\frac{1}{10}$  of a unit increase in the atomic weight of chlorine requires a cut of 18,600, the second requires only one of 6,300, while the corresponding values for neon are 19,600 and 1,710, so the second increase of 0.1 unit in the atomic weight of neon requires only  $\frac{1}{10}$  the cut. However, from the practical standpoint the great number of fractional diffusions necessary to keep the quantity of material large enough to proceed with the operations, makes each successive  $\frac{1}{10}$  unit increase very much more difficult to attain.

#### Apparatus for the Diffusion of Gases at Atmospheric Pressure.

Of the methods for the diffusion of a gas through a porous wall, there is little doubt that the most efficient is what is termed a vacuum diffusion, in which the gas diffuses through the wall into as high a vacuum as can be maintained. The pressure on the high pressure or "heavy fraction" side of the wall is kept at a magnitude which is dependent upon the diameter of the pores in the wall, and at such a value (for example 10 mm. of mercury) that the mean free path of the gas is as great as the diameter of the pores, which should be a uniform diameter. The low pressure of the gas insures not only a molecular passage of the gas through the pores, but it also aids greatly in securing a good mixing of the gas.

There are, however, several objections to the diffusion at low pressures: (1) it is difficult to make the process automatic; (2) the volume of the gas per unit mass is greatly increased; and (3) it necessitates a more cumbersome method of collecting the heavy and light fractions. For these reasons it was decided, since a fair efficiency had been obtained in a separation of known gases, and particularly since a very good (about 60%) efficiency had been obtained in the separation of the isotopes of chlorine by Mr. Broeker

by diffusing at atmospheric pressure, to delay the use of the vacuum method until after the difference in atomic weight of the chlorine separated by this method had been definitely established by the use of this partly automatic apparatus.

The general procedure adopted is to generate hydrogen chloride at atmospheric pressure by dropping conc. sulfuric acid into conc. hydrochloric acid from a height of about 90 cm.,—in order to secure good mixing of the acids. After the first diffusion the sulfuric acid was dropped upon sodium chloride. The dried gas is passed through porous porcelain tubes, and the lighter fraction which consists of the diffusate which passes through the walls is swept away by a rapid current of purified air. The heavy fraction is that which passes through the system of tubes and remains inside. Both fractions are absorbed by condensation in the *surface* of a considerable amount of water. The apparatus though quite similar to that used in this laboratory by Dr. Turner and by Mr. Broeker, but not described by them, is greatly improved in many particulars. It was designed to care for 1000 liters of hydrogen chloride per day, at atmospheric pressure.

Only acids of high purity were used in the work, and the hydrogen chloride produced came in contact with only pure sulfuric acid, glass, porous porcelain, and a very small area of paraffin, from the time it left the generators until it was absorbed in distilled water of the "conductivity" grade.

Since according to the Rayleigh theory the enrichment of the heavy fraction with respect to the heavy constituent depends only upon the fraction of the original gas that remains inside the diffusion tubes, and since this fraction changes very rapidly with the rate at which the gas is fed into them from the generator, a flow meter was placed in the line leading from the generator, and the evolution of gas was so regulated that the flowmeter gave a constant reading.

Flowmeters were also placed in all of the air sweep-out lines for each diffusion tube jacket, since it was necessary to reduce the partial pressure of the hydrogen chloride in the diffusate to a very low value as soon as it escapes from the walls of the diffusion tubes, and since otherwise a back diffusion will greatly lower the efficiency of the process.

A 20-liter bottle (1), with a tall dropping head, serves as a generator for the first diffusion. Six liters of c. p. hydrochloric acid is introduced into this bottle through the dropping funnel (2). For each 6 liters of this acid about 8 liters of conc. c. p. sulfuric acid is dropped into it from a very wide 24-liter supply bottle (3). The flow of acid after it is started, is controlled by the 3-way stopcock, (4), the supply being sufficient to run for 23 hours. By refilling the generator at about 4.00 P.M. each day, a very steady flow of gas is secured through the night, the regulation requiring no attention between 10.00 P.M. and 7.30 A.M. When the speed of generation begins to fall in the morning, the generator is heated to 50° by means of an air-bath heated on an electric hot plate. By this means 75% of the hydrochloric acid in the original acid can be

recovered. The generator is emptied by means of pressure through the siphon (4) directly into a carboy. For all succeeding diffusions the gas is generated in a 2-liter or a still smaller flask (5) into which sulfuric acid is dropped from a funnel (6). When the speed of evolution of gas from this generator falls, it is heated to 100°, thus giving nearly 100% recovery of the hydrogen chloride.

The trap (7) is to prevent an explosion of the generator, which otherwise is likely to occur if the generator happens to foam over, since the warm sulfuric acid solution of sodium hydrogen sulfate will solidify very quickly when it reaches the cold tubes. This usually clogs the tubes, and an explosion is apt to result, but has never occurred when the trap is in the system.

From the generators the hydrogen chloride passes into the trap (8) which collects moisture and sulfuric acid spray and through the flowmeter (9). Sulfuric acid is used as the manometer liquid in all of the flowmeters, and its injection into the apparatus is prevented by the traps (10). The bulb (11) is used to prevent sulfuric acid from being drawn back into the flowmeter (10) from the gas dryer (12). The thistle tube and its connections on (12) served to introduce fresh acid into the dryer, and also as a manometer to measure the pressure at the generator end of the diffusion train. The drying acid in (12) is renewed every second day. The bulb (13) is filled with glass wool, tightly packed, to filter out all sulfuric acid spray from the dried gas. After passing this the gas goes directly into the first diffusion tube (14). The first diffusion tubes are the stems of churchwarden pipes, while the succeeding ones were especially prepared for our use by the Ceramics Division of the Bureau of Standards. The latter are one meter long, 11 mm. outside diameter, with 2 mm. walls. They are sealed into glass tubes of almost the same diameter by the use of plaster of Paris. The diffusion tubes were then sealed into glass jackets 1.5 meters long, and 5 cm. in diameter. The air for sweeping out the diffusate enters the jackets through the two tubes (15) and passes out of it through the three tubes (16). These three exit tubes for each jacket are assembled into a single line leading to the absorbers for the light fraction. During the first diffusion the material from the first diffusion unit is absorbed in distilled water in absorber (17) and is designated as the light fraction from the first diffusion. During later diffusions of the heavy fraction this absorber is shunted out of the line, since its capacity is too great. The diffusate from the succeeding 4 jackets is absorbed in the large absorber (18) and when the concentration of the solution reaches 6 *N*, it is turned back into the stock of the laboratory (not, however, for any diffusion after the first) as dil. chemically pure hydrochloric acid. It is free from sulfites, sulfates, organic matter, and gives no test for iodine or bromine. The heavy fraction, or that which remains inside of the tubes at the end of the fifth or last unit, is absorbed in the absorber (19).

In the third and fourth diffusions only the first two units are used, and the small absorber (20) is used for the heavy fraction. Very large 3-way stopcocks (22) are between each two diffusion units, so that the apparatus may be used as two or more separate diffusion trains. The series of bulbs and the dropping funnel (21) constitute a sulfuric acid dryer for the heavy fraction passing from the fifth unit to the absorber (19), its purpose being to prevent any moisture from the absorber from reaching the porous tubes. The absorbers were all made on the same plan, and consist of two or more horizontal, and usually very large, glass tubes, arranged one above the other. Each of these tubes is provided with a gas inlet tube at one end, and an outlet tube at the other, and also with a tube and stopcock for allowing the acid to be dropped into the next unit below, or, on the bottom or first unit, for drawing it off from the apparatus.

The horizontal tubes are filled nearly full of pure distilled water thus leaving a long narrow passage for the gas. Nearly all of the hydrogen chloride is absorbed in the first unit, and none of this gas can be detected by the odor at the exit from the last tube.

When the solution in the first or bottom tube reaches 6*N* in concentration, it is drawn off, the solution in each of the other tubes is dropped into the tube just below it, and distilled water is poured into the last or uppermost tube. This change can be made during the operation of the apparatus, while the method of surface absorption makes it possible to keep the pressure in the tubes very close to that of the external atmosphere, and to balance properly the pressures inside and outside the tubes, so that no capillary transpiration may occur.

The air supply for sweeping out the diffusate from the jackets comes from the compressed air supply of the laboratory, and is passed into an empty bottle (23) for settling out impurities, then through 30% caustic soda solution in the very large bottle (24), through the safety bottle (25), through conc. sulfuric acid in a very large bottle (26), and is then blown on the surface of conc. sulfuric acid in the bottle (27). It is then filtered through a foot of glass wool (28) and a foot of absorbent cotton (29), and passes into the distribution line (30). From this it flows through individual stopcocks (31), through flowmeters (32), past sulfuric acid manometers (33), through traps (34) into the jackets of each unit. The traps are used to prevent sulfuric acid from getting into the diffusion units from the manometers or flowmeters. The manometer (35) and that at (12) serve to give the gas pressure in the diffusion line, while those designated as (33) indicate that in the jackets.

Air is passed through each jacket at the rate of 3 liters per minute. During the first diffusion hydrogen chloride passes flowmeter (9) at the rate of 600 cc. per minute, and at this rate  $\frac{1}{30}$  of it arrives at the absorber for the heavy fraction (19) and is collected there. For the second diffusion gas is generated at the same rate, but only four of the units are used. This gives a cut of 20. Third diffusions are run with only the first two units, gas being generated at the rate of 200 cc. per minute, and again a cut of 20 results. The total cut  $30 \times 20 \times 20$ , or 12,000, should, according to the Rayleigh theory, give an atomic weight for the chlorine in the heavy fraction of 35.54, but it is hardly to be expected that an efficiency of 100% in terms of this theory can be obtained, except possibly in a vacuum diffusion, under ideal conditions.

The heavy fraction from each diffusion is neutralized with very pure sodium hydrogen carbonate, and is used in the generator which uses salt (5) for the regeneration of the hydrogen chloride. It is found that the generation from sodium chloride occurs at a more uniform rate if carried out at a temperature of 80° until the charge is nearly spent, when the temperature is rapidly raised to 100°. If the generator at the middle of the run is giving off gas at the rate of over 300 cc. per minute, the salt cake will adhere to the bottom of the flask, until enough sulfuric acid has been run in to float it. Just as it comes loose from the bottom of the flask there is a violent evolution of gas. At rates below 300 cc. per minute the cake is gradually wetted throughout with sulfuric acid and the difficulty is avoided.

It is evident that the process of diffusion may be carried out fractionally and this was done. Thus the light fraction from the second diffusion has nearly as high a density as the heavy fraction from the first diffusion, so it is not rejected, but is rediffused, and the heavy fraction which results has nearly as high a density as that of the original second diffusion.

### Method of Analysis and Calculation of Results.

In order to be able to determine the effects of the successive diffusions it is important to develop a method of determining with considerable precision the change of atomic weight produced. It was found that such

a method could be devised easily provided a simple and seemingly accurate hypothesis is adopted as its basis. This is that isotopes have so nearly the same atomic volumes and the same chemical properties, that no error of sufficient magnitude to affect the analyses will be introduced if it is assumed that they are exactly alike in these respects. That the isotopes of lead have the same volume within the limits of the experimental error has been shown by Soddy<sup>11</sup> and by Richards<sup>12</sup> and that their identity in chemical properties is almost complete is shown by a joint investigation by Gale, Aronberg, and one of the writers,<sup>13</sup> since they found that the difference in the wave length of the line  $\lambda 4058$  caused by a difference of about 0.9 in the atomic weight, was only one-millionth of the wave length. The difference in chemical properties between these isotopes may be expected to be very small. This discovery has been confirmed by Merton.<sup>11</sup> However, even though this hypothesis is used as a basis for calculation, the proof that a *separation* of the two isotopes of chlorine has been made is *entirely independent* of the assumption, since no differences of atomic volume could be detected unless a separation had first been effected.

The simplest method for determining the increase of atomic weight was thought to be the determination of the densities of specimens of highly purified ordinary hydrochloric acid, and a comparison with these of the density of a specimen of acid produced by diffusion. This will be termed the isotopic acid, and the plan was to fix the molecular concentrations of these two acids as determined by titration, at the same value, and to compare the weights of hydrogen chloride which they contain. It is evident that the weight of the isotopic acid should be greater than that of the ordinary or "comparison" acid, since the present article refers to the heavy fraction. These weights are in the same ratio as the formula weights of hydrogen chloride in the two solutions, so

$$\text{and} \quad M_i = 36.468 \cdot W_i/W_c \quad (13)$$

$$A_i = M_i - 1.008 \quad (14)$$

$$\text{or} \quad \Delta A = 36.468 \Delta W/W_c. \quad (15)$$

Here  $M_i$  and  $A_i$  are the molecular weight of hydrogen chloride and the atomic weight of chlorine, respectively,  $W_i$  and  $W_c$  are the weights in grams of the hydrogen chloride in the same volumes (e. g., pycnometer full) of the comparison and the isotopic acids, and  $\Delta W$  is the increase in weight which occurs when the isotopic acid is substituted for the comparison acid. Equation 15 gives the most accurate results, since it does not

<sup>11</sup> Soddy, *Nature*, 94, 615 (1915).

<sup>13</sup> Harkins and Aronberg, *Proc. Nat. Acad. Sci.*, 3, 710-15 (1917); *THIS JOURNAL*, 42, 1328-35 (1920); Aronberg, *Astrophys. J.*, 47, 96-103 (1918); Merton, *Proc. Roy. Soc. London*, 96A, 388-95 (1920).

involve an exact knowledge of the weight in solution of either the comparison or the isotopic acid, but only a precise value for the increase in weight. The thermostat should be regulated to  $0.001^\circ$  or better, and the pycnometer should consist of a large spherical bulb with a short but very narrow neck graduated with a very fine line at its narrowest point. Above the neck is a bulb large enough to hold any solution which rises through the neck on account of thermal expansion. This is fitted with a very close fitting ground-glass stopper, and with very fine tubes for filling and emptying. The pycnometer is preferably made of quartz, and the tubes of platinum or hard gold.

While the above procedure is the simpler from the standpoint of the equations involved, it happens that another method is more economical of time and material, so what has actually been done in most of the cases is to adjust the comparison and the isotopic acids to the same density, and to determine the number of molecules of hydrogen chloride, and therefore the number of atoms of chlorine, present by titration. In this case the acid in the pycnometer has a higher molecular concentration when the comparison acid is used. Very accurate density determinations have been made on solutions of very pure ordinary hydrochloric acid by Dull in this laboratory. From his data it may be calculated that the "apparent density" of hydrogen chloride in 5.91 *N* hydrogen chloride is 1.785, in 5.79 *N* it is 1.7852, while in 5.20 *N* it is 1.787, and in 2.315 *N* it is 1.856.

The difference in the titration values of the comparison and the isotopic acids may easily be calculated in the following way for any desired increase in the atomic weight ( $-\Delta A$ ) of chlorine. Calculate the increase of weight which would occur if the comparison acid in the pycnometer were to be replaced by isotopic acid of the same titration value. Then calculate the number of equivalents of hydrogen chloride in the isotopic acid which must be replaced by water of a density 0.997077 (or 0.99604 as weighed by brass weights in air, if the temperature of the thermostat is  $25^\circ$ ) in order to reduce its weight by the above difference. This gives the difference in the titration values of the two solutions when adjusted to the same density, which will be given directly in terms of 0.01 *N* sodium hydroxide solution, since the titration was completed with a base of this concentration, though begun with 1 *N* solution.

$$\Delta T = \frac{V \cdot N \Delta A}{1000 \cdot M_c} \cdot \frac{d\text{HCl}}{d\text{HCl} - d\text{H}_2\text{O}} \cdot \frac{1}{10^{-5}} \quad (16)$$

$$\text{or} \quad \Delta A = 100 \cdot \Delta T \cdot \frac{d\text{HCl} - d\text{H}_2\text{O}}{d\text{HCl}} \cdot \frac{M_c}{V \cdot N} \quad (17)$$

Here the symbols have the same meaning as before, except that the following new ones are employed:  $M_c$  is the equivalent weight of hydrogen chloride in the comparison acid, and equals 36.468 in the present experi-

ments;  $N$  is the normality of the comparison acid;  $d\text{HCl}$  is the apparent density of hydrogen chloride in the comparison acid;  $d\text{H}_2\text{O}$  is the density of water at the same temperature;  $\Delta T$  is the difference in grams of  $1/100$  weight normal sodium hydroxide between the pycnometer full of the two acids;  $10^{-5}$  is the number of equivalents of sodium hydroxide in 1 cc. of 0.01  $N$  base.  $V$  is the volume of pycnometer in cc. If  $V$  cc. is titrated, the right hand side of the Equation (17) for  $\Delta A$  should evidently be multiplied by  $V/v$ .

Let  $T'_c$  and  $T'_i$  represent the titration values of the comparison and isotopic solutions in terms of normal solutions, then it is evident that Equation 17 may be given the following form.

$$\Delta A = \left( \frac{T'_c}{T'_i} - 1 \right) \frac{d\text{HCl} - d\text{H}_2\text{O}}{d\text{HCl}} \cdot M_c \quad (18)$$

**Method of Adjusting the Densities of the Isotopic and Comparison Acids.**—After a preliminary determination of the densities of the two solutions, the concentration of the solution was read from a graph giving concentrations in terms of the density of ordinary pure hydrogen chloride, and from these values the amount of water necessary to decrease the concentration of the more concentrated solution to that of the more dilute was calculated. This first adjustment brought the densities of the solutions sufficiently close so that a difference of 5 or 6 mg. was all that remained for a volume equal to that of the pycnometer.

A second dilution was made by adding water up to the exact amount called for by the equation  $(d_1 d_2 - d_2) \cdot W_w = W_s (d_2 d_1)$ , where  $d_1$  is the smaller, and  $d_2$  the larger density,  $W_w$  is the weight of water to be added to the weight  $W_s$  of the more dense solution in order to make the densities the same. This equation is not exact, since it takes no account of the volume change produced in adding water to approximately 6  $N$  acid, so it does not bring the two weights closer together than 0.6 mg. An exact equation could easily be developed, but even with the form used only 0.2 g. of water needed to be added to 75 g. of solution in the third dilution.

**Error of Filling.**—The pycnometer could be filled repeatedly with a *maximum* variation of 0.0012%, while the usual error was considerably less. The thermostat was constant to within less than 0.001°.

**Method of Titration.**—First a series of indicator standards was made up in 125cc. tightly glass-stoppered Erlenmeyer flasks.<sup>14</sup> In each of these was put the same volume of conductivity water and the same amount of methyl orange as was used in the titrations. To these were added in order 0, 2, 4, and 6 drops of 0.01  $N$  hydrochloric acid. The titrations

<sup>14</sup> Flasks with very narrow necks will be used for all future work, so that the evaporation may be decreased.

were ended at a color between that in the 2-drop and the 4-drop flasks, and in good daylight the effect of one drop of 0.01 *N* base could be readily detected. A 1 *N* solution of sodium hydroxide was used to carry the titration to within one drop of the end-point, when it was finished with 0.01 *N* solution of the same base. Weight burets of 60 g. capacity were used and these were weighed on a balance sensitive to 0.02 mg. It was found that the use of a heavy "vacuum" stopcock grease completely stopped all loss of weight of the burets due to evaporation of the solutions through the ground-glass stopcocks.

The samples for titration were weighed by measuring 5 cc. of the 6 *N* solution, dropping it into the flask, and then determining the weight on the same balance as that used for the pycnometer. The ground-glass stoppers in the sample flasks were kept dry during the whole determination.

**Purification of Acid.**—The acid used in the analyses as the reference or comparison acid was the light fraction from the first diffusion. A calculation showed that its atomic weight could not have been changed sufficiently to be detectable, and the process used would result in a considerable purification. The acid was treated with potassium permanganate and boiled to expel any iodine, bromine, or chlorine liberated, and was then distilled, rejecting the first third and the last one-fourth.

The isotopic acid was purified in several ways. As has been stated it was formed by the action of very pure sulfuric upon *c. p.* hydrochloric acid. The gas came in contact with only carefully cleaned and dried glass and porous porcelain, and was absorbed in conductivity water. After the second diffusion the salt formed by neutralizing the acid by very pure sodium hydrogen carbonate was recrystallized three times from pure water and was very thoroughly drained and washed with pure water each time. The mother liquor from these crystallizations showed no trace of iodine by the use of a test which would detect one part of iodine as iodide in twenty thousand parts of sodium chloride, as determined by repeated tests. This test consisted in the use of nitrosyl sulfuric acid and carbon disulfide with the proper precautions. Neither could bromine be detected in these mother liquors, but we did not rely upon this fact to insure the absence of bromine. In addition to these three crystallizations, the acid, after the third diffusion was treated with potassium permanganate and distilled using exactly the method employed with the comparison acid, except that the first and last fourths were rejected and the middle half was saved. Additional purifications were made by precipitation of sodium chloride from aqueous solution by the addition of isotopic hydrogen chloride. The sodium hydroxide used in the analyses gave no test for bromine. It was converted into sodium chloride and recrystallized, and the mother

liquor again gave no test for bromine. However, after the sodium hydroxide was added to any sample the latter was always purified carefully.

### Results.

In January, 1920, Mr. C. E. Broeker had produced about 5 g. of hydrogen chloride which was the heavy fraction given by a cut of about 8000. Shortly afterward this was increased to about 20 g. with nearly as large a cut. However, the analyses made in January by Harkins and Broeker used nothing but the original sample. The purification of the acid was made by recrystallization of sodium chloride. In purifying most of the operations are carried out before the sample has been reduced to such a small mass, but at least one purification is always carried out with the final residue. The titration values indicated increases of atomic weight of 0.052, 0.059, 0.057, 0.055, and 0.053 units of atomic weight. A second series of analyses on another sample, gave slightly higher values.

Mr. Broeker's work was interrupted by illness in April, 1920, but on account of his unusual enthusiasm and energy he continued to work for two weeks after his illness began. Since just at this time he adopted a new system of labeling, and his illness took an unexpected turn for the worse and finally resulted in his death, it happened that his records were not completed, and this resulted in some uncertainty in identifying his samples. For this reason, and for the additional purpose of demonstrating that the separation could be carried out by the use of an independent apparatus, and by using different materials, an entirely independent diffusion was started. The hydrogen chloride obtained in the present series of diffusions will be added, in the form of sodium chloride, to the sodium chloride obtained by him, as soon as the atomic weight has increased by the amount given above.

It should be realized that in work of this kind it is not merely the increase in atomic weight which counts, but also the amount of material which is obtained, since the future progress of the work, and also the extent to which the material can be purified, depends largely upon the amount of material available. While the rise in atomic weight obtained in the independent series of diffusions carried out this year, is not large, it seems to be definite, and of the order of magnitude to be expected from the earlier results given above, so a report of progress will be given.

**Analysis of the Purified Third Diffusion Residue (Cut = 12,000).—**In order that the magnitude of the errors involved may be realized the actual data for some of the analyses will be presented. First the reference acid and the isotopic acid were adjusted to practically the same density in a Harkins' pycnometer of about 22cc. volume. The weights were as follows:

100 g. of chlorine obtained of atomic weight 35.494.

<sup>a</sup> The absolute humidity in mm. of mercury is represented by *h*.

<sup>b</sup> The weights of base and acid used in these titrations are reduced to the same barometric pressure and the same humidity for each series.

The corrections of about 0.0018 for the results of the first, and of 0.0016 for the results of the second series were calculated from the density differences by means of the same equation as was used for the calculation of the results of the titrations.

The difference between the averages of the atomic weights for the first and second series of analyses is 0.0038 units of atomic weight which is very near the possible error in the atomic weight of chlorine according to Richards. While the data given indicate that the comparison method described is a very accurate one for the determination of the atomic weight of an isotope of chlorine, our experience has shown that its precision may be increased, provided as large quantities of acid are available, by the observance of certain precautions which may be introduced. The atomic weight of the chlorine produced by diffusion by the writers is very close to 35.494, while that obtained by Harkins and Broecker was 35.515. However, the amount of material produced by the present work is very much greater, since a few days more of diffusion will give about 100 g. of acid with this atomic weight for the chlorine. Since the efficiency of the process as conducted has not proved to be very high in terms of the Rayleigh diffusion theory, it is planned to conduct the rest of the diffusions upon the smaller portions now on hand, by a vacuum system of diffusion, which should give a high efficiency. The apparatus which is to be used will be described in the next report, and will be similar in many respects to that developed in this laboratory by Dr. Turner for the diffusion of chlorine. Since the amounts of material to be handled are now greatly reduced a further increase of from 0.05 to 0.1 units in addition to that already secured should be obtained quite rapidly, but the rapidity of increase will be dependent upon the amount of the material secured, since a small increase with a large yield of material may be more difficult to secure than a larger increase on a small amount of material.

**Repurified Fourth Diffusion Residue** (Cut = 240,000).<sup>15</sup>—The hydrochloric acid obtained from the third diffusion had been converted largely into sodium chloride in the titrations on the third diffusion residue, so the remaining acid was neutralized with sodium hydrogen carbonate. The salt thus obtained was converted into hydrogen chloride, and again diffused. The hydrochloric acid thus obtained was distilled fractionally, after heating with potassium permanganate. The middle portion was used for the analyses reported below.

Nine g. of chlorine of atomic weight 35.498 was obtained in this diffusion. The fourth diffusion was not so efficient as the first three, since the

<sup>15</sup> Report added to paper on May 16, 1921. Determinations by Anson Hayes and S. K. Allison.

apparatus is better designed for larger samples, and in this diffusion the gas passed through only a short length of porous tube of large diameter.

### Result of Additional Purifications.<sup>16</sup>

As has been stated, all of the acid used in this series of determinations was purified after the second diffusion by conversion into sodium chloride through neutralization with very pure sodium hydrogen carbonate, and by three successive fractional crystallizations from pure water. The highly concentrated *mother liquor* from all of these crystallizations, after removing a part of the salt content, gave no test for iodine or bromine. The hydrochloric acid obtained from this salt was, nevertheless, heated with potassium permanganate, and fractionally distilled.

In order to remove all possible doubt in regard to the presence of such impurities, it seemed advisable to make still further purifications. However, this could not be done successfully, using the methods developed for this work, on the 9g. sample of the fourth diffusion residue, since the purification involves the rejection of the greater part of the acid used. The sample was therefore obtained largely by diffusing the *light* fraction from the third diffusion, and adding the considerable quantity of acid thus obtained to the fourth diffusion residue. Since the fourth diffusion had not proved very efficient, the sample thus obtained should have an atomic weight not far from that obtained in the third diffusion residue.

The acid obtained in this way was heated with potassium permanganate and distilled fractionally. The middle portion was neutralized with very pure sodium hydrogen carbonate. Part of the salt thus obtained was then dissolved in 35 cc. of conductivity water, and precipitated by passing in hydrogen chloride generated from the remainder of the isotopic sodium chloride. This purified salt after the hydrochloric acid had been drained off thoroughly was again separated into two portions, and the process was repeated. The apparatus used was wholly of glass.

The 9 g. of sodium chloride thus obtained was carefully separated from the considerable amount of liquid, and the acid still remaining on the salt was driven off by heating in platinum to 300°. The salt was again converted into hydrochloric acid, and was then distilled fractionally. The distillate was again redistilled, and the resulting isotopic acid used in the determinations.

The comparison acid used was subjected to exactly the same set of purifications and treatment using the same apparatus and the same materials, the only difference being that it had not been subjected to the diffusion process. The density determinations and the analyses are given herewith.

<sup>16</sup> Atomic weight determination by Anson Hayes and S. K. Allison. Report added June 9, 1921.

	Increase in atomic weight above 45.46		0.0318
	Atomic Weight = 35.4918		

While the above results are all that were obtained under the best conditions on this particular sample, since the other samples were of necessity allowed to stand overnight, two additional titrations of the isotope were then obtained as follows: 19.5974, and 19.6001 g. of  $N$  NaOH to titrate 10 g. of isotopic acid. These confirmed the result obtained above as to its general magnitude, but gave a determination which was slightly more in error. It had been found that under the conditions under which these samples stood, the titration value is very slightly increased, so the atomic weight obtained, from these two titrations, 35.4886, is probably too low. The atomic weight determination for this series is slightly less accurate than for the three preceding series, as the amount of material used was less.

## Summary.

1. A definite increase in the atomic weight of chlorine has been obtained in experiments conducted in this laboratory by the diffusion of hydrogen chloride at atmospheric pressure. The increase in atomic weight amounts in different experiments to from slightly less than to considerably more than one part in a thousand (1 in 645). The amount of separation obtained is in a certain sense considerably more than might be supposed from this figure, since a considerable amount of this isotopic acid has been produced. This seems to be the first separation of isotopes reported from which there is any definite evidence.

2. The separation of isotopes by diffusion is discussed in terms of the Rayleigh diffusion equation, which applies to a diffusion into a vacuum. It is indicated that for a high efficiency the pressure of the gas on both sides of the diffusion wall should be low, first in order to secure good mixing, and second to insure that the passage through the porous partition shall be entirely molecular. Since the large amounts of acid used in the preliminary diffusions have now been largely reduced, the further work in this laboratory will be carried out at low pressures, and with porous material in which the pores are very small.

3. A method which is at the same time very precise and very rapid has been devised for the determination of the atomic weight of any isotopic form of chlorine.

4. It is found that in the separation of isotopes the percentages present of the different isotopes are as important factors as the atomic weight differences. Thus, contrary to what has been supposed, it is shown, even aside from the greater difficulties involved in obtaining and handling neon, that it is easier in terms of the cut necessary to produce a small increase in the atomic weight of chlorine (of the magnitude of 0.05 units) than to produce the same increase in the atomic weight of neon.

5. In January, 1920, Harkins and Broeker had separated 5 g. of isotopic chlorine (in the form of hydrogen chloride) of an atomic weight 35.515. Preliminary notices of this separation were published in the February, 1920, number of the *Physical Review*, in *Science*, and in *Nature*. The present research was begun in order to confirm the earlier work, in June 1920, and has thus far used none of the material left by Mr. Broeker at the time of his death in April 1920. An apparatus of higher capacity, but somewhat lower percentage efficiency, has been used. Nine g. of chlorine of atomic weight 35.498, and 90 g. of atomic weight 35.494, have been obtained, the atomic weight results having been determined upon very highly purified material. In addition to this considerable isotopic chlorine of lower atomic weight has been obtained, about 400 g., whose atomic weight has not been determined, but should be more than 0.02 units higher, and 4 kg., whose atomic weight should be more than 0.01 unit higher, than for normal chlorine, judging from the efficiency of the whole process. Dr. W. D. Turner prepared several kg. of this last grade in the summer of 1918, and about 20 g. of much more highly diffused chlorine in 1916-7, but the atomic weight work was left incomplete on account of the war. A notice of the beginning of this work was published in THIS JOURNAL in January, 1916. In 1915, definite evidence based upon atomic weight relations was presented by one of the writers that chlorine consists of isotopes. An important feature of the present investigation is that it was begun four years before any entirely direct experiments had proved the existence of isotopes in chlorine, and a

notice of the separation was published only two months after Aston's preliminary notice in regard to their existence.

The writers wish to express their indebtedness to the C. M. Warren Fund of the American Academy of Arts and Sciences for a grant of five hundred dollars to be used in carrying on the present investigation. A part of this has been used in the purchase of an analytical balance sensitive (for a  $1/2$  mm. deflection) to  $1/100$  mg. to be used in weighing small samples of higher or lower atomic weight. Thanks are also due to the Wolcott Gibbs Fund of the National Academy of Sciences for a similar grant to be used in determining the effects of radiation and high temperatures upon the stability of the nucleus of the atom, and also for positive ray work upon isotopes. We wish to thank the Grasselli Chemical Company of Cleveland, Ohio, and the Mallinckrodt Chemical Company of St. Louis for gifts of considerable amounts of hydrochloric and sulfuric acids; the Jaques Mfg. Co. for a barrel of sodium hydrogen carbonate which proved to be purer than the "analyzed" material previously purchased; Dr. F. L. Dunlap for his assistance in securing material; T. H. Liggett and S. K. Allison for assistance in the experimental work; and the Bureau of Standards and the Coors Porcelain Company for the preparation of tubes of different porosities.

Diffusions on the light fraction were carried out by C. E. Broeker in the year 1919-20, and the results of this work will be reported in a later paper. It is hoped that funds for the construction of a centrifugal machine may be secured, as it seems probable that the centrifugal method, or at least some method other than those of diffusion, thermal diffusion, or vaporization at low pressures, must be used if a separation of any considerable magnitude is to be obtained without the expenditure of an unreasonable amount of effort.

**COMPOUND FORMATION AND VISCOSITY IN SOLUTIONS  
OF THE TYPES ACID : ESTER, ACID : KETONE, AND ACID : ACID.**

BY JAMES KENDALL AND ELIZABETH BRAKELEY.

Received May 16, 1921.

In a recent article<sup>1</sup> the complete specific conductivity-composition curves for a number of systems of the above types have been presented, and their significance with respect to the fundamental relationship between compound formation and ionization in solutions, as postulated in previous papers,<sup>2,3</sup> critically examined. The point was made clear in the discussion, however, that for a strict comparison of ionization equilibria throughout the different systems a knowledge of other variables was necessary. Among these variables the first in importance is viscosity.

In the present communication the viscosity—composition curves for certain of the above systems are given, not so much with the idea of making immediate and final corrections in the corresponding specific conductivity curves as with the hope of obtaining additional and confirmatory information regarding the relative extent and stability of compound formation between the components in such systems. When progress in other lines has been made, the results here obtained will of course ultimately be of service in making exact corrections upon the conductivity data. The present impossibility of such a procedure, however, is discussed in a later section.

### Experimental.

The following systems have been investigated: (a) *acid:ester systems*, trichloro-acetic acid and acetic acid with ethyl acetate and ethyl benzoate; (b) *acid-ketone systems*, trichloro-acetic acid and acetic acid with acetone and acetophenone; (c) *acid:acid systems*, trichloro-acetic acid with acetic acid.<sup>4</sup>

The same careful methods of purification of the substances employed, described in earlier articles<sup>5,6</sup> were followed, and materials of the same high order of purity, as evidenced by suitable physical constants in each case, were obtained throughout. The apparatus used for the determination of viscosities was of the Bingham type.<sup>6,7</sup> The experimental procedure was essentially as given in previous work,<sup>8</sup> the only new feature

<sup>1</sup> Kendall and Gross, *THIS JOURNAL*, **43**, 1426 (1921).

<sup>2</sup> Kendall and Booge, *ibid.*, **39**, 2323 (1917).

<sup>3</sup> Kendall and Gross, *ibid.*, **43**, 1416 (1921).

<sup>4</sup> Other examples of this type (and of its extension into the type: acid-base) have been taken up by previous investigators. The results obtained by them are utilized in the discussion below.

<sup>5</sup> Kendall and Wright, *THIS JOURNAL*, **42**, 1776 (1920).

<sup>6</sup> Bingham, *J. Ind. Eng. Chem.*, **6**, 233 (1914).

<sup>8</sup> Kendall and Monroe, *ibid.*, **39**, 1787 (1917).

presented being the necessity of adopting particular precautions for the protection of the materials employed against water vapor, the hygroscopic character of certain of the substances used (*e. g.*, trichloro-acetic acid<sup>9</sup>) being very pronounced.

TABLE I.  
PROPERTIES OF PURE COMPONENTS.

Liquid.	Freezing pt. °C.	Boiling pt. (760 mm.) °C.	Density. 25°/4°.	Viscosity. 25°.	Spec. conductivity. (mhos) 25°.
Ethyl acetate	....	77.1 ± 0.05	0.8948	0.004236	1 × 10 <sup>-9</sup>
Ethyl benzoate <sup>10</sup>	....	212.9 ± 0.1	1.0458	0.01982	1 × 10 <sup>-9</sup>
Acetone <sup>11</sup>	....	....	0.7872	0.003065	6 × 10 <sup>-8</sup>
Acetophenone	....	202.3 ± 0.1	1.0263	0.01681	5.5 × 10 <sup>-8</sup>
Acetic acid <sup>12</sup>	16.57 ± 0.05	117.8 ± 0.1	1.0499	0.01121	2.4 × 10 <sup>-8</sup>
Trichloro-acetic acid <sup>13</sup>	59.2	....	(1.62)	(0.0683)	(3 × 10 <sup>-9</sup> )

The viscosity results obtained for the various systems at 25° are presented in the tables below. Density data are also appended, to enable transformation of the results from molecular percentages to volume percentages to be made if desired. With the Bingham viscometer, very accurate density determinations are not necessary,<sup>14</sup> and the values given are not to be relied upon beyond the third decimal place. The mixtures investigated being essentially non-ideal, linearity in the density-volume composition curve is not to be expected. In some of the systems, considerable heat effects were evident on admixture.

TABLE II.  
TRICHLORO-ACETIC ACID : ETHYL ACETATE.

11.18	0.9972	0.005878
18.40	1.045	0.007309
28.07	1.123	0.01001
38.46	1.202	0.01449

TABLE III.  
ACETIC ACID : ETHYL ACETATE.

Mol. % acid.	d <sub>4</sub> <sup>25</sup> .	Viscosity.
0.00	0.8948	0.004236
10.49	0.9092	0.004590
20.70	0.9211	0.004949
30.37	0.9308	0.005331
39.90	0.9417	0.005762

<sup>9</sup> Work with this substance was confined to cold, dry days.

<sup>10</sup> The density here obtained is slightly greater than that given by Kendall and Wright (*Ref. 5*); the viscosity is slightly less, but practically identical with the former value of Kendall and Monroe. The boiling-point recorded in Kendall and Wright's article (*p. 778*) is in error, the value for a preliminary sample having been accidentally substituted.

<sup>11</sup> Jones and Mahin (*Am. Chem. J.*, 41, 440 (1909)) quote a much higher viscosity for acetone. The result here given, however, is very close to the interpolated value of Thorpe and Rodger (*Phil. Trans.*, 185A, 397 (1894)) and to the more recent value of Dunstan and Hilditch (*Z. Elektrochem.*, 18, 186 (1912)).

<sup>12</sup> Dunstan (*Z. physik. Chem.*, 51, 732 (1905)) gives a higher viscosity value, but the present result is again in good agreement with Thorpe and Rodger's data.

<sup>13</sup> The values given are extrapolated from measurements at higher temperatures, as described later.

<sup>14</sup> The density enters into the working formula only in a correction factor (approximately 1% of the total), hence approximate values are sufficient. In a few cases the figures given are interpolated results.

## Consideration of Results.

The majority of the systems with trichloro-acetic acid as one component are reproduced in diagram form in Fig. 1; those with acetic acid as one component are shown in Fig. 2.

Fig. 1.—Trichloro-acetic acid systems. I. Trichloro-acetic acid:ethyl acetate; II. Trichloro-acetic acid:acetone (subtract 0.005 from viscosity scale); III. Trichloro-acetic acid:acetophenone; IV. Trichloro-acetic acid:acetic acid,

It will be noticed that the trichloro-acetic acid curves are incomplete. This is due to the fact that pure trichloro-acetic acid melts at  $59.4^{\circ}$ ; consequently solutions containing more than 70 mol. % (approximately) of trichloro-acetic acid begin to solidify at temperatures above  $25^{\circ}$ . In a few cases slightly supercooled solutions were successfully investigated at this temperature. With any large excess of acid, however, crystallization during the determinations, stopping up the capillary and rendering all measurements impossible, could not be prevented.

Fig. 2.—Acetic acid systems. I. Acetic acid: ethyl acetate; II. Acetic acid: acetone (add 0.002 to viscosity scale); III. Acetic acid: acetophenone.

An approximate value for the viscosity of pure trichloro-acetic acid at  $25^{\circ}$  was derived by making measurements with an Ostwald viscometer in a small bath at two temperatures above its melting point and extrapolating the results. At  $60^{\circ}$  the density and viscosity were 1.595 and 0.0397 respectively, and at  $70^{\circ}$  they were 1.588 and 0.0315. By linear extrapolation the viscosity at  $25^{\circ}$  is 0.0683; in view of the uncertainty of the extrapolation<sup>15</sup> and the relatively large experimental errors involved in the Ostwald method of measuring viscosity this figure must be regarded as merely indicative.

The position of the point for pure trichloro-acetic acid on the diagram

<sup>15</sup> Viscosity is not, of course, a linear function of temperature, but the various relationships proposed for normal liquids (Batschinski, *Z. physik. Chem.*, 84, 643 (1913); Arrhenius, *Meddel. K. Vetenskapskad. Nobelinst.*, 3, No. 20 (1918)) will certainly not be applicable to an associated liquid such as trichloro-acetic acid. Linear extrapolation is here adopted as the simplest possible procedure and cannot, in view of the shortness of the temperature interval, involve any extreme error.

(Fig. 1), however, makes it evident that the viscosity curves for all systems examined containing this acid as one component exhibit a very sharp maximum in the neighborhood of 80 to 90 mol. % acid. The existence of such a maximum must be ascribed, in each case, to the extensive formation of complex addition compounds of higher viscosity than the pure components. It was at one time common practice<sup>16</sup> to deduce the formulas for such addition compounds from the position of the maximum on the composition axis. The fallacy of such a procedure has been exposed by Findlay<sup>17</sup> and by Denison,<sup>18</sup> who have employed the more logical method of marking the position of maximum deviation from the normal curve rather than the actual maximum point. Unfortunately, in the case of viscosities, we have not yet succeeded in establishing the ideal curve<sup>19</sup> all that we know with certainty is that it is not linear but considerably sagged. We cannot therefore postulate, from examination of the above curves, what compounds are present in the solutions. We are justified, however, in regarding the curves as confirming the fact, already indicated by freezing-point data, that addition compounds are formed in quantity in all cases.

The curves with acetic acid as one component are of a different nature. Only in one system here studied (acetic acid:acetophenone) is a maximum obtained, and even this is exceedingly flat. While we can legitimately draw, from this, the conclusion (also previously indicated by freezing-point data<sup>20,21</sup>) that compound formation is in general much less extensive in systems of esters and ketones with acetic acid than in systems of the same substances with trichloro-acetic acid, yet the absence of a maximum must not be taken to signify that compound formation is entirely absent. Thus the curve for the system acetic acid:acetone is not sagged throughout, but shows a point of inflection; while the curve for the system acetic acid:ethyl benzoate is entirely concave (instead of convex) towards the composition axis. Compounds are evidently present in solution in these cases in quantity sufficient to raise the curves considerably above their normal position, but insufficient to produce an actual maximum. Even in the curve for the system acetic acid:ethyl acetate, which is sagged and apparently ideal throughout, compound formation is undoubtedly a factor, for acetic acid is a typical associated liquid and the addition of a substance entirely inert towards it would normally result in a viscosity curve with a minimum point, due to the progressive disassociation of the acetic acid into less viscous simple molecules as its concentration in the

<sup>16</sup> For references see Walden, *Akrens' Sammlung*, 15, 397 (1910).

<sup>17</sup> Findlay, *Z. physik. Chem.*, 69, 217 (1909).

<sup>18</sup> Denison, *Trans. Faraday Soc.*, 8, 35 (1912).

<sup>19</sup> See Kendall and Monroe, *THIS JOURNAL*, 43, 115 (1921).

<sup>20</sup> Kendall and Booge, *ibid.*, 39, 1712 (1916).

<sup>21</sup> Kendall and Gibbons, *ibid.*, 37, 149 (1915).

solution diminishes.<sup>22</sup> Compound formation, in this case, must approximately counterbalance such disassociation. In the other systems, for the same reason, the true extent of compound formation must be greater than that which is apparent from the shape of the curves (particularly in a case such as acetic acid: acetone, where *both* components of the system are highly associated liquids), owing to the obscuring effect of the disassociation factor.

**Systems of the Type Acid:Acid and Acid:Base.**—The one system of the type acid:acid here examined (trichloro-acetic acid:acetic acid) gives a sharp maximum on the viscosity curve (see Fig. 1), although at 25° this maximum cannot be experimentally realized owing to its proximity to the trichloro-acetic acid side of the diagram. The viscosity results thus confirm the extensive formation of addition compounds between the two acids of widely divergent acidic strengths previously suggested by freezing-point depression measurements.<sup>23</sup> It is of importance to note that the viscosity curve for the system acetic acid:sulfuric acid<sup>24</sup> also shows a maximum. In this case the existence of an equimolecular compound ( $\text{CH}_3\text{COOH}$ ,  $\text{H}_2\text{SO}_4$ ), with melting point  $-2.5^\circ$ , has been directly established by examination of the freezing-point curve.<sup>25</sup> With acids of similar acidic strength, however, (*e. g.*, formic acid,<sup>26</sup> propionic acid) acetic acid gives a typically sagged curve, indicating that compound formation is practically non-existent.

When we consider acetic acid with bases, increasing diversity again involves increasing compound formation and the maximum reappears. Thus acetic acid:formamide<sup>27</sup> and acetic acid:water<sup>28</sup> both show curves with comparatively flat maxima. With a still stronger base, (acetic acid:aniline<sup>29</sup>) the maximum becomes very sharp, flattening out only at high temperatures.

Many other examples of the type acid:base, of similar character, have been investigated by previous workers. It will suffice here to mention the curve for the system sulfuric acid:water<sup>30</sup> (which gives a very sharp maximum corresponding to the very stable compound  $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$ ) and the recent work of Bramley<sup>31</sup> on systems of the type phenol: aniline.

**Application of a Viscosity Correction to Conductivity Data.**—Walden<sup>32</sup> has shown that for a fixed solute (tetra-ethylammonium iodide) in a series of very divergent solvents the product of  $\Lambda_{\infty}$  and  $\eta$  is practically a constant; in other words, the mobilities of the ions are inversely proportional to the viscosity of the medium. If Walden's rule could be directly extended to the systems investigated in this paper, we could at once transform the specific conductivities as determined by Kendall and Gross to relative ionic concentrations by multiplying throughout by the viscosity of each particular solution. Considerable doubt has been cast by subsequent workers<sup>33</sup> in this field, however, upon the general validity of Walden's rule, and the conditions here existent are so different from those in the solutions examined by Walden that we are compelled to hesitate in making this step until more definite advances have been made, lest by attempting to compare our results on a false basis we arrive at entirely unjustified conclusions.

Walden worked with a single solute only<sup>34</sup> (and that a salt, as recent work indicates,<sup>35</sup> of exceptional character) at very low concentrations. In any particular solvent, therefore, the degree of solvation of the ions would not appreciably vary. In the present work, we are dealing with solutions with compositions ranging all the way from pure component A to pure component B, and the average ionic complexity will undoubtedly change very significantly with composition.<sup>36</sup> In the case of aqueous solutions of salts at moderate concentrations, Green<sup>37</sup> and Washburn<sup>38</sup> have established that a fractional power viscosity correction is more accurate than a linear correction, presumably on account of decreasing hydration of the ions with decreasing water concentration.<sup>39</sup> Here, with a much more extended concentration range, viscosity variations are so enormous (over 1000% in some systems) that the value of the exponent in any fractional power correction would need to be very accurately

<sup>32</sup> Walden, *Z. physik. Chem.*, **55**, 246 (1906).

<sup>33</sup> For example, Fitzgerald has shown that  $\Lambda_{\infty}\eta$  is by no means constant for salts in liquid ammonia, sulfur dioxide and water (*J. Phys. Chem.*, **16**, 645 (1912)). For further references see Kraus, *THIS JOURNAL*, **36**, 35 (1914); Ghosh, *J. Chem. Soc.*, **117**, 1390 (1920).

<sup>34</sup> In an article which has just appeared (*Z. anorg. Chem.*, **113**, 85 (1920)) Walden has tried to extend his rule to other solutes, partly answering and partly admitting the objections made by other investigators.

<sup>35</sup> Ghosh, *J. Chem. Soc.*, **113**, 630 (1918); Walden, *Z. physik. Chem.*, **94**, 295 (1920).

<sup>36</sup> See Kendall and Gross, *THIS JOURNAL*, **43**, 1436 (1921).

<sup>37</sup> Green, *J. Chem. Soc.*, **93**, 2049 (1908).

<sup>38</sup> Washburn, *THIS JOURNAL*, **33**, 1461 (1911).

<sup>39</sup> Similarly Johnston (*ibid.*, **31**, 1010 (1909)) found a fractional power relationship to exist between  $\Lambda_{\infty}$  and  $\eta$  as temperature is varied. Schlesinger and Coleman, however, in the case of metal formates in formic acid solutions, claim that no viscosity correction at all is to be applied (*ibid.*, **38**, 271 (1916)).

determined to fix the final position of a curve. Since, furthermore, different systems might very conceivably require quite different exponents and would almost certainly give significantly different values for the product  $\Delta_{\infty}\eta$ , any rigorous comparison at this stage is obviously altogether impracticable.

As has been shown above, however, the viscosity results in themselves furnish us with considerable additional information on compound formation in the systems studied, confirming very strongly the rule that compound formation is fundamentally dependent upon diversity in character of the constituent groups of the components, and the data here presented will later, it is hoped, be utilized in making exact and dependable corrections upon the conductivity results of Kendall and Gross.

### Summary.

The viscosity-composition curves for the following systems at 25° have been determined: (1) trichloro-acetic acid:ethyl acetate, (2) acetic acid:ethyl acetate, (3) trichloro-acetic acid:ethyl benzoate, (4) acetic acid:ethyl benzoate, (5) trichloro-acetic acid:acetone, (6) acetic acid:acetone, (7) trichloro-acetic acid:acetophenone, (8) acetic acid:acetophenone, (9) trichloro-acetic acid:acetic acid.

The results obtained indicate extensive compound formation in solutions of the esters and ketones with a strong acid (trichloro-acetic). The same substances with a weak acid (acetic) give viscosity curves which are much less abnormal, although compound formation is still evident. The curve for the system trichloro-acetic acid:acetic acid exhibits considerable compound formation, and an examination of the results of previous workers on systems of the types acid:acid and acid:base shows that this behavior is general, except when the components are of similar acidic strength. The rules formulated in previous articles relating the extent of compound formation with diversity in character of the components are hereby confirmed.

The results here presented may ultimately be employed to place the specific conductivity data obtained by Kendall and Gross for the same systems upon a strictly comparable basis. The difficulties which prevent this step being made immediately have been briefly discussed.

## THE MEASUREMENT OF DIELECTRIC CONSTANTS.

BY J. F. KING AND W. A. PATRICK.

Received May 19, 1921.

This preliminary paper contains a description of a bridge method for measuring dielectric constants of liquids in which use is made of audion bulbs both as a source of exciting current and as a means of determining the balance point of the bridge. Our interest in the dielectric constant is due to the suspected close relationship that exists between this constant and the solvent power of liquids. That there is a relation between the swelling powers of liquids and their dielectric constants is apparent from a casual review of the experimental data. However, there are many exceptions to the rule and our effort is directed toward the possibility of finding a more general relationship.

Accordingly, we planned first to measure the dielectric constants of a series of liquids and mixtures of the same and also the swelling power, or as it is incorrectly called the "solvent" power, that these exerted upon a certain sample of cellulose nitrate.

Our choice of a suitable method for the measurement of dielectric constant was greatly influenced by the result of a year's work in this field by one of the authors. This work (unpublished) was done in University College, London, together with Professor F. G. Donnan and resulted in the conviction that there is no satisfactory method for the measurement of dielectric constant of liquids possessing a specific conductivity greater than that of conductivity water. In this work the Drude<sup>1</sup> method as well as Schmidt's<sup>2</sup> modification was carefully investigated, using a well constructed apparatus in which special attention was paid to the exciting energy and the end-point detectors. A 30cm. spark induction coil was employed, operated with a mercury break interrupter. This induction coil was connected to a Tesla converter, the energy from which was used to excite the primary circuit of the testing apparatus. Neon tubes were prepared and the most sensitive ones were used in determining the end-point. The results of the experiments with this apparatus showed that neither from the standpoint of precision nor from the standpoint of the ability to measure the dielectric constants of conducting liquids, does this apparatus have the advantages which have been claimed for it over other methods. When liquids that possessed a conductivity only slightly greater than that of conductivity water were used, the minima became very obscure, and furthermore during the measurement a large increase in the temperature of the liquid was observed, indicating that energy

<sup>1</sup> Drude, *Z. physik. Chem.*, 23, 267 (1897).

<sup>2</sup> Schmidt, *ibid.*, 27, 343 (1898).

absorption was taking place. This energy absorption increased with the increase in frequency of the electric wave. This is important from the chemist's viewpoint since it is commonly understood that an increase in the frequency of the electric wave enables one to measure the dielectric constant of a conducting liquid.

Many experiments were made with the well-known bridge method as developed by Nernst.<sup>3</sup> Special attention was given here to the source of alternating current. Electrically driven tuning forks of various frequencies within the telephonic range were used, as well as a variety of other well-known interrupters. The sharpest minima, however, were obtained with a small Wehnelt break. All manner of changes in the apparatus did not develop an arrangement which was especially satisfactory. The principal objection was the lack of precision. The sources of current producing the more symmetrical electric waves gave minima which extended over a large portion of the setting scale.

From a theoretical consideration of the distribution of an alternating current in a Wheatstone bridge, we decided to use as our source of alternating current an apparatus which would furnish a symmetrical wave. This is an important factor in the measurement of dielectric constant for the assurance of a sharp and true minima. Professor Flemming<sup>4</sup> has given it consideration in his statement, "It may be pointed out incidentally that no accurate balance or well defined zero can be obtained unless the electromotive force applied to the bridge has a very true sine wave form. Hence no arrangement such as a buzzer, hummer or current interrupter of any kind can be substituted for the sine curve alternator or for an alternator and a wave filter."

We used a frequency of about 1000 cycles per second since this is within the telephonic range and gives a pitch easy to detect and since there is nothing to be gained by using a higher frequency. The work of one of us cited above showed that there is greater energy absorption at higher frequencies. Flemming has treated this matter theoretically and has shown that greater dissipation of current due to the dielectric occurs at higher frequencies. With a slightly conducting liquid in our cell we have to measure the capacity similar to that of a leaky condenser. Flemming has shown that the energy loss in a poor dielectric due to an alternating current can be divided into two parts, the first due to conductivity which is probably electrolytic in nature and the second to a conductivity which is nearly proportional to the frequency. The first is the regular direct current conductance while the second has been called an alternating current conductance.

In the method worked out by Nernst, the ratio arms of the bridge

<sup>3</sup> Nernst, *Z. physik. Chem.*, **14**, 622 (1894).

<sup>4</sup> Fleming, *Proc. Phys. Soc. London*, [2] **23**, 117 (1911).

consisted of two resistances and the other arms consisted of an unknown capacity which was balanced by a measuring condenser. In order to make the impedance in the ratio arms of the same magnitude as the impedance in the balancing arms, it was necessary to use very large resistances with the possibility of introducing self-induction into those arms of the bridge. We used air condensers in all four arms. Air condensers are to be desired because of their more constant capacity and the smaller chance for leakage.

Since, with a conducting solution in our dielectric cell condenser, we had to balance a leaky condenser, we used a non-inductive resistance shunted around the measuring condenser in the balancing arm of the bridge. Although Flemming<sup>4</sup> has shown that it is not possible to duplicate a leaky condenser by means of a condenser and a resistance in parallel, we were able to prove that up to a certain limiting value of shunted conductivity it was possible to obtain true values of the capacity of the condenser.

Much attention has been given by conductivity workers and workers on the bridge method for the measurement of dielectrics to the phone used to detect the minima. The minimum current possible in the bridge is determined by the current necessary to excite the phones. This minimum current is still large enough to cause trouble in the matter of heating effects, polarization, etc. A small current is to be desired, but using a small current and one of symmetrical wave form much difficulty is experienced in reaching a minimum. To overcome this difficulty we used the thermo-ionic amplifier of recent development. With this improved apparatus, consisting of a source of alternating current of symmetrical wave form, a symmetrical bridge, each arm of which offered an impedance of the same magnitude, and with an extremely small current flowing through the bridge, the use of which was made possible by the amplifier in connection with the telephones, we hoped for an improvement in the accuracy of our measurements.

The Vreeland oscillator is without doubt the best source of alternating current of sine wave form, but the cost of the Vreeland oscillator led us to turn to the electron tube as our source of current. By an arrangement in which an electron tube, a condenser and an induction coil are connected in a circuit, it is possible to obtain an alternating current of symmetrical wave form. With this arrangement by properly varying the plate voltage, the temperature of the filament, the capacity and the induction, it is possible to obtain different currents varying from a few tenths of a milliamperer or less to 25 amperes and with a frequency varying from  $\frac{1}{2}$  cycle per second to 50 million cycles per second.<sup>5</sup>

## DIELECTRIC CONSTANT APPARATUS

We used the "Marconi Vacuum Tube" type V.T.1. In the drawing, T is the vacuum tube, C the condenser, and I the induction coils. The audion plate was charged with 120 volts by dry cells while the filament was heated with a current of 0.7 ampere and 4 volts supplied from lead storage cells. The two induction coils consisted of about 300 turns of No. 32 wire each wound around a laminated iron core. The lead to the bridge was coupled to this with about 50 turns on the secondary coil. At C are two variable Murdock condensers connected in parallel. By adjustment of these condensers we obtained a frequency of about 1000 cycles per second. During the first part of our work we used the laboratory current to charge the plates in the electron tubes both in the amplifier and in the oscillator. Great difficulty was experienced from external noises caused from other electrical apparatus running in the building which tended to obscure the minimum and greatly tried the patience of the operator; but when dry cells were used to supplant the laboratory current the results were most gratifying.

In the construction of the bridge, two variable Murdock air condensers were used in the ratio arms.<sup>5</sup> The condensers had a capacity of about 0.0005 microfarad and the scales were divided into 180 divisions. In any series of measurements these condensers were set and the moving pointer sealed by means of sealing wax. These condensers

<sup>5</sup> These condensers as well as most of the wireless apparatus were purchased from the Wireless Specialty Co. of Boston.

are represented by  $C_1$  and  $C_2$  in the drawing. In the measuring arm of the bridge were the following parts.

1. A variable vernier condenser,  $C_3$  in the drawing, "DeForest" type, with a capacity of 0.0015 microfarad. The scale was divided into 100 divisions. The vernier had a capacity of about 180 degrees per scale division. The pointer on this scale was extended about 75 cm. to an enlarged scale of some 2200 divisions of 1 mm. each, thus enabling us to set the condenser with a much greater precision. In making a measurement, the setting was made on the large scale and then the accuracy of the scale was tested by means of the vernier condenser. The vernier was moved by means of a lever operated from the center of the room. This was done to prevent the introduction of capacity into the bridge from the operator's body. If after making a setting on the large scale, the vernier, by a small movement to the right and to the left, passed through a minimum, we assumed the setting to be correct.

2. Connected in parallel with this measuring condenser was a second Murdock condenser,  $C_3'$ , from which about half of the plates had been removed. The recording pointer of this condenser was also extended to an enlarged scale. It was possible to use the large condenser for changes in dielectric from 2 to about 26 and over and the small condenser for changes from 2 to 7, gaining a 5-fold increase in sensitivity. The vernier setting-lever was used for testing the setting of the minimum when either condenser was used. When  $C_3$  was used,  $C_3'$  was locked in a fixed position, the scale of  $C_3$  calibrated and the measurements made. When it was desired to use  $C_3'$  as the measuring condenser,  $C_3$  was locked and the small condenser scale was calibrated.

3.  $R_1$  is a non-inductive resistance made by filling a conical glass tube with "Manganin" solution (121 g. of mannitol plus 41 g. of boric acid). The resistance of this tube could be varied by varying the distance between the electrodes or by moving a plunger down into the ground glass conical part of the tube, thereby decreasing the cross section. The stem of the plunger fitted into a hard rubber cap which was threaded. The small thread on the screw of the cap made possible a very sharp setting of the resistance. This was extremely important when any great conductivity was possessed by the liquid being measured. In some cases it was found that turning the cap one or two mm., involving the very slight accompanying displacement of the plunger in the tube, entirely obscured the minimum. Previous workers have called attention to the importance of the resistance used to compensate the conductivity. It has been suggested that as the conductivity increased and the electrodes in the liquid resistance were moved closer together, a capacity was introduced in the resistance tube which involved an error in the capacity of the measuring condenser. That this is not the true explanation can easily be shown by a consideration of the voltage consumption in the measuring arm of the bridge. A simple calculation is sufficient to illustrate this point.

Consider the bridge, with capacities  $C_1$  and  $C_2$  balanced against capacities  $C_3$  and  $C_4$  the latter being shunted with resistances  $R_1$  and  $R_2$  respectively. Then  $Z_1/Z_2 = Z_3/Z_4$  where  $Z$  is the impedance; if  $C_1 = C_2$ , and both  $C_1$  and  $C_2$  are air condensers,  $Z_1 = Z_2$ , and therefore  $Z_3 = Z_4$ .

Let us suppose that  $C_4$  is composed of 2 concentric cylinders 0.2 cm. apart and having an electrode surface of 50 sq. cm. Furthermore, let the dielectric be alcohol having a dielectric constant of 25 and a specific conductivity of  $1 \times 10^{-7}$  mho.

The capacity of such a condenser is  $Ka/4\pi d$   $900,000 = 0.00055$  mf. The resistance of such a cell is therefore  $(50/0.2) \times 10^{-7} = 2.5 \times 10^{-5}$  mho  $= 0.4 \times 10^6$  ohm.

The impedance of the above capacity and resistance in parallel may be most easily calculated by obtaining the vectorial sum of the admittances due to capacity and resistance. The admittance due to capacity at a frequency of 1000 is  $2\pi \cdot 1000C = 2 \times 3.1416 \times 1000 \times 5 \times 10^{-10} = 3.1 \times 10^{-6}$ . Therefore the admittance of the combina-

tion is  $\sqrt{(2.5 \times 10^{-5})^2 + (3.1 \times 10^{-6})^2} = 2.52 \times 10^{-5}$ . The impedance is  $1/2.52 \times 10^{-5} = 0.396 \times 10^5$  ohm.

This calculation shows that the impedance of the whole bridge arm is largely determined by that of the resistance alone and that the quantity which we wish to measure, the capacity, only slightly affects the total impedance. In other words, an accurate measurement of capacity cannot be made at a frequency of 1000 cycles per second if the impedance due to resistance is less than that due to capacity. This is an important consideration for the determination of the limit of conductivity. It has been commonly overlooked in dielectric-constant measurements of conducting solutions.

4. In the fourth arm of the bridge was a condenser,  $C_4$ , shunted by a Mangani solution resistance. This condenser acted as a tare condenser and the resistance was used to balance the conductivity of the liquid when the dielectric cell condenser was placed on the  $C_3$  arm of the bridge in the differential method of measurement which was used. Our purpose in finally adopting the differential method was to eliminate any errors due to an unsymmetrical arrangement of the bridge such as different self-inductances of the wires, mutual capacities of the condensers, etc. Also by the differential method twice the ordinary displacement on the measuring scale is obtained for a given change in dielectric.

The dielectric cell was composed of two co-axial platinum cylinders, 2.2 cm.  $\times$  6.3 cm. and 1.9 cm.  $\times$  6.3 cm., respectively, which were set in the ground glass stopper of a glass cup. This cup was mounted on a hard rubber base. The platinum cylinders were firmly fastened at each end to prevent any possible displacement during a set of measurements. These cylinders as well as the cup were easily cleaned between measurements by washing several times with alcohol and ether and then drying in a stream of air. It was so arranged that the whole dielectric cell could be placed in a holder in a thermostat if at any time the accuracy of the work should demand close temperature control. The dielectric cell was arranged by means of a rocking commutator so that it could be placed in parallel first with  $C_4$  and a reading taken and then in parallel with  $C_3$  and the difference in reading taken. During the calibration of the scale and during any series of measurements,  $C_1$ ,  $C_2$ , and  $C_4$  were sealed,  $C_3$  being the only condenser whose capacity was changed.

The amplifier was a two-step type triode E to which a third step was added by means of an amplifying transformer and an electron tube, thus giving a 1000 fold amplification. The plates were charged at 40 volts from dry cells and the filaments were heated by a current of 0.7 ampere and 6 volts from lead storage cells. This amplifier was used in connection with a set of Baldwin wireless telephones. These telephones have non-adjustable mica diaphragms and were especially suited for wireless work for the reception of very weak signals. Their resistance was 2000 ohms. In any determination, the amplifier was adjusted by changing the temperature of the filaments to give the greatest sensitivity and then was not changed during an entire calibration and set of measurements. This was in keeping with the care always exercised during a set of readings to vary nothing but the liquid in the dielectric cell and the capacity of the measuring condenser. It was only by employing the greatest precaution along these lines that consistent and comparable results could be obtained. For instance, before the rocking commutator was used in the differential method of measurement, a wire was moved from  $C_4$  to  $C_3$  in order to change the dielectric cell from parallel with  $C_4$  to parallel with  $C_3$ . It was discovered that the movements of this fine short wire caused the shifting of the minimum many divisions on the recording scale. Again, before the final setting was made by the use of the vernier condenser lever operated at a distance from the bridge, it was found that effects produced by the operator's body either entirely obscured the minimum or shifted it a few hundred divisions.

The first set of measurements on the bridge was made for the purpose of determining the sensitivity of the apparatus. Before using the differential method it was found that we were able to get very sharp minima when the ratio of the condensers in the ratio arms was other than one to one. This made it possible to magnify the deflection of the dielectric cell on the measuring condenser. With benzene in  $C_4$ , the dielectric cell,  $C_3$  the measuring condenser gave in 4 experiments, 430, 430, 430, and 390; with ether it gave 840, 905, 1070, and 1205, respectively.

In the last measurement a change in dielectric of from 2.22 to 4.35 caused a change on the setting scale of the measuring condenser of 815 divisions, which means (setting to one division on the scale and one division is one millimeter) that one division on the scale is equivalent to a change in dielectric of 0.0026. These measurements could be made on  $C_3'$ . When made on  $C_3'$  which possessed a 5-fold sensitivity, one scale division was equivalent to a change in dielectric of 0.0005. No attempt was made to carry this study further as it was not desired to reach this sensitivity. For our measurements we needed a sensitivity which would keep the readings of a change in dielectric of from 2 to 26 on the scale.

A set of measurements was made by the differential method and the same satisfactory balancing of the bridge was obtained.

Investigation was next made of the effect of an added non-inductive resistance to an air condenser whose capacity was being measured by the differential method. This resistance was balanced out by a resistance in parallel to the condenser in the balancing arm.

	<i>a.</i>	<i>b.</i>	<i>a-b.</i>	<i>diff.</i>
Condenser alone .....	497	293	204	..
Condenser plus resistance in parallel .....	505	260	245	41

As the resistance decreased, the difference between the true capacity and the observed capacity increased. Next a 22,000-ohm resistance was shunted around the condenser whose capacity was being measured. As the capacity was increased, the amount that the minimum was shifted due to the shunted resistance decreased. It was also found that there was less shifting of the minimum due to the shunted resistance if the ratio condensers as 1:1. The reason for this can be seen from the following calculation.

If the impedance of the ratio arms is the same, *i. e.*, if  $C_1 = C_2$ , then  $C_3 = C_4$  in the presence of conductivity due to  $R$  only on condition that  $C_3$  is shunted with an equal resistance. On the other hand, if  $C_1$  does not equal  $C_2$ , the ratio of  $C_3$  to  $C_4$  will not equal the ratio of  $C_1$  to  $C_2$  even under the condition that  $R_3$  is equal to  $R_4$ . A single calculation is sufficient to bring out this point.

Let  $C/C_2 = a/b$ ; then  $Z_3/Z_4 = b/a$ ; or  $A_3/A_4 = a/b$  (1)  
 where  $Z$  is the impedance, and  $A$  is the admittance. Further let  $R_3 = R_4 = x$ .  $A$   
 = the vectorial sum of  $C_3 + (1/x)$ .

$$= \sqrt{C_3^2 + (1/x^2)}; \text{ and } A = \sqrt{C_4^2 + (1/x^2)}.$$

$$\text{From Eq. 1 } a \sqrt{C_4^2 + 1/x^2} = b \sqrt{C_3^2 + 1/x^2}.$$

$$\text{Squaring, } a^2 C_4^2 + \frac{a^2}{x^2} = b^2 C_3^2 + \frac{b^2}{x^2}$$

$$b^2 C_3^2 - \frac{a^2 - b^2}{x^2} = a^2 + C_4^2 \quad (2)$$

$$\frac{b^2 C_3^2}{a^2 C_4^2} = 1 + \frac{a^2 - b^2}{a^2 C_4^2 x^2}$$

$$\frac{C_3^2}{C_4^2} = \frac{a^2}{b^2} + \frac{a^2 (a^2 - b^2)}{b^2 a^2 C_4^2 x^2}$$

$$\frac{C_3}{C_4} = \frac{a}{b} + \sqrt{\frac{a^2 - b^2}{b^2}} - \frac{1}{C_4 x}. \quad (3)$$

From this general equation one can see that the ratio of  $C_3$  to  $C_4$  is equal to the ratio of  $C_1$  to  $C_2$  only when the product  $C_4 x$  is large. Inasmuch as  $C$  is the capacity of the condenser being measured we can increase the product only by working with dielectrics of small conductivities, that is of large values of  $x$ . In other words, it is possible to obtain a greater sensitivity by making the ratio of the ratio condensers greater than 1; however, this cannot be done for liquids having appreciable conductivity.

The effect of the introduction of the maximum conductivity of the Mangani resistance tubes shunted around an air condenser was studied. As shown by the following observation, no appreciable shifting of the minimum resulted.

	<i>a</i> .	<i>b</i> .	<i>a-b</i> .
Air condenser alone .....	1488	321	1167
Air condenser plus maximum conductivity of resistance tube .....	1498	330	1168

The same results were obtained when the dielectric cell was used.

Dielectric cell alone,

	<i>a</i> .	<i>b</i> .	<i>a-b</i> .
Empty .....	1636	1588	48
Filled with ether .....	1701	1523	178
Dielectric cell plus maximum conductivity of resistance tube,			
Empty .....	1633	1585	48
Filled with ether .....	1700	1522	178

In all measurements of dielectric constants only those liquids were measured whose conductivity could be balanced out with the tested Mangani solution resistances.

The condensers in the ratio arms were now set at 90, *i. e.*, at a ratio of 1:1, condensers  $C_1$ ,  $C_2$ , and  $C_4$  were sealed,  $C_3$  was locked into position and the scale on  $C_3$  was calibrated by filling the dielectric cell with the above liquids. The calibration curve is given on the chart with the curves for the dielectric measurements.

Liquid.	CALIBRATION DATA.			
	D. C.	a.	b.	a-b.
Carbon tetrachloride.....	2.25	1268	1160	108
Ether.....	4.35	1320	1115	205
$C_6H_6 + C_6H_5NO_2$ .....	15.9	1380	860	720
Alcohol.....	25.8	1795	640	1155

The following tables give the results of the dielectric measurements of the different mixtures with interpolation values from the curves. The points on the calibration curve were re-checked between measurements so as to assure no change in the values of the bridge. The liquids were not allowed to stand exposed to the air during a measurement, because in some cases the conductivity increase due to the absorption of water vapor from the air was such as to introduce an error in the observed value of the capacity of the dielectric cell. The conductivity of alcohol was observed to increase considerably upon exposure to the air for a few seconds. At the end of a half hour or less the conductivity had increased beyond that which could be balanced out with the maximum conductivity of the Manganin resistances.

## ORGANOGEELS OF SILICIC ACID.

BY B. S. NEUHAUSEN AND W. A. PATRICK.

Received May 23, 1921.

As is well known Graham<sup>1</sup> was able to prepare silicic acid gels which contained large percentages of organic liquids, such as alcohol, ether, glycerine, and only very small amounts of water. Owing to the large percentage of organic liquids that were contained in the organogels, and from the ease with which he could replace one liquid by another by allowing the gel to soak in the liquid, *viz.*, transformation of an alcogel into an ether gel, Graham was led to some interesting conclusions: "The various organic liquids are capable of displacing the combined water of silicic acid hydrate, whether that hydrate is in the liquid or gelatinous condition, and give new products. The production of the compounds of silicic acid indicates the possession of a wider range of affinity by a colloid than could well be anticipated. Thus, of hydrated silicic acid the combined water leaves the acid to diffuse into the alcohol, and if the alcohol be repeatedly changed the *entire* water is thus removed, alcohol at the same time taking the place of the water in combination with the silicic acid. The process is reversed if an alcogel be placed in a considerable volume of water. Such changes illustrate the predominating influence of mass."

Because of Graham's experimental results and his conclusions which enjoy wide acceptance, the question arose whether we could prepare a hard gel composed of only silica and an organic liquid. This seemed very probable, since in the alcogel as prepared and analyzed by Graham there were 383 parts of alcohol to 1 part of water. It was thought that by heating the gel at a high temperature in a vacuum, an organic gel practically water-free could be obtained.

## Preparation of the Gels.

The hydrogel of silica was prepared in the usual way from water glass and hydrochloric acid. The gel was washed free from chlorides, squeezed to remove as much water as possible, and then placed in 95% alcohol. Another sample was put into C. P. acetone. After the gel had remained in the alcohol for 24 hours it was squeezed dry of liquid and transferred to a fresh sample of alcohol. This treatment was repeated four times. The gel was then placed in a sample of alcohol that had been refluxed over lime for several days, and allowed to stand for two days. This treatment with the anhydrous alcohol was repeated four times.

<sup>1</sup> Graham, *J. Chem. Soc.*, 17, 318 (1864); *Pogg. Ann.*, 123, 529 (1864).

A sample of the gel that had undergone the above treatment was heated in a vacuum of 5 mm. for 1 hour at 80°, 1 hour at 120°, and finally for 1 hour at 270°.

The acetone gel was put through a similar process. It was given four treatments of 24 hours' duration in c. p. acetone, and finally four treatments at 48-hour intervals in redistilled acetone (b. p. 56.5°).

A portion of the alcogel as it came from the last soaking in alcohol was transferred to redistilled benzene and allowed to remain in this liquid for 2 days. This treatment was repeated six times, when a sample failed to give the iodoform test for alcohol. This benzene gel was heated in a vacuum like the others.

### Analytical Results.

The three gels were analyzed by the regular combustion methods of organic chemistry. Towards the end of the combustion the boat containing the gel was heated to about 900° in order to drive all the water out of the gel. From the amounts of carbon dioxide and water formed, the percentages of alcohol, acetone, or benzene, as well as that of water in the gel were calculated. A typical analysis follows.

	I. G.	II. G.
Wt. of acetone gel .....	1.343	0.860
H <sub>2</sub> O produced by combustion .....	0.111	0.0712
CO <sub>2</sub> produced by combustion .....	0.115	0.0732
Calculated weight of acetone .....	0.0505	0.0322
Water from acetone .....	0.0470	0.0300
Excess water .....	0.0640	0.0412
% Acetone in gel .....	3.76	3.74
% Water in gel .....	4.76	4.78

The analytical results are tabulated below.

	% water.	%.
Alcogel	4.23	3.90 alcohol
Acetone gel	4.77	3.75 acetone
Benzene gel	4.31	3.82 benzene

### Discussion.

From the above results it is apparent that Graham was in error when he stated that it is possible to replace all the water from a silica hydrogel by other liquids. We have shown in this laboratory that silica gel may be heated to 300° in a vacuum produced by a Gaede pump for a period of 6 hours without reducing the water content below 4.8%. It is not surprising, therefore, that soaking in anhydrous alcohol as above described does not remove all the water. It is evident that the residual small percentage of water in silica gel is held with a force that exceeds that exhibited between the atoms of many stable compounds. Subsequent work in this laboratory has shown that this water can be removed at high

temperatures without affecting appreciably the structure of the gel as exhibited by its adsorption ability.

### Summary.

It is impossible to remove all the water from the hydrogel of silicic acid by repeated immersions in anhydrous alcohol, acetone, or benzene.

## COMPOUND FORMATION AND CONDUCTIVITY IN SYSTEMS OF THE TYPES FORMIC ACID:METAL FORMATE AND SULFURIC ACID:METAL SULFATE.

BY JAMES KENDALL, HOWARD ADLER AND ARTHUR W. DAVIDSON.

Received June 6, 1921.

In a recent investigation<sup>1</sup> on systems of the types acid:ester, acid:ketone and acid:acid it has been shown that the specific conductivities of such binary mixtures increase regularly with increasing compound formation between the components. Strong support was thereby obtained for the validity of the hypothesis, formulated in earlier articles,<sup>2,3</sup> that ionization in solutions is primarily dependent upon the preliminary formation of unstable solvent-solute complexes. In subsequent communications<sup>4,5</sup> it has also been established that compound formation in systems of the general type  $HX:RX$  increases in extent with increasing diversity in the positions of the radicals H and R in the electrode potential series. The present work continues the study of systems of this type by examining how far the parallelism between compound formation and conductivity can be traced in them. As experimental material, the two series previously investigated with respect to compound formation (metal formates in formic acid and metal sulfates in sulfuric acid) have naturally been chosen.

Very accurate determinations upon the conductivities of the alkali and alkaline earth formates in anhydrous formic acid have been carried out by Schlesinger and his co-workers,<sup>6</sup> so that only a few additional data were required in this series. In the case of sulfuric acid:metal sulfate systems, the results of previous investigations proved to be much less dependable.

<sup>2</sup> Kendall and Booge, *ibid.*, **39**, 2323 (1917).

<sup>3</sup> Kendall and Gross, *ibid.*, **43**, 1416 (1921).

<sup>4</sup> Kendall and Davidson, *ibid.*, **43**, 979 (1921).

<sup>5</sup> Kendall and Adler, *ibid.*, **43**, 1470 (1921).

<sup>6</sup> Schlesinger, *et. al.*, *ibid.*, **33**, 1924 (1911); **36**, 1589 (1914); **38**, 271 (1916); **41**, 72, 1921, 1934 (1919).

For correlation with these two series, we have also extensive data immediately available for a third series of precisely the same type—metal hydroxides in water. A sufficient variation in the acid radical X (from the strong acid  $\text{H}_2\text{SO}_4$ , through the intermediate acid  $\text{HCOOH}$ , to the very weak acid  $\text{HOH}$ ) is thus obtained to enable us to test the effect of changes in this radical upon the nature of the results, and to extend any generalizations deduced over the whole field  $\text{HX} : \text{RX}$ .

### Systems of the Type, Formic Acid : Metal Formate.

Schlesinger has demonstrated that the alkali formates are extensively dissociated in formic acid solution, and that very satisfactory ionization constants can be obtained for each salt through a wide range of concentrations without the application of any viscosity correction to the conductivity data. The alkali earth formates also<sup>6</sup> are highly ionized in anhydrous formic acid, and give good ionization constants throughout a somewhat more limited range if it is assumed that they behave, in moderately concentrated solutions, as uni-univalent electrolytes.<sup>7</sup> It is possible that the mutual cancellation of counterbalancing factors may account for this somewhat unexpected vindication of the Ostwald dilution law in both cases, but the ionization constants for the different salts as calculated by Schlesinger can certainly be safely utilized as indicative of the order of their strengths as bases<sup>8</sup> in formic acid solution, which is all that is needed for the purpose of the present investigation.

Conductivity determinations have here been carried out upon 3 salts not studied by Schlesinger, namely, barium, magnesium and lead formates. In order not to trench too deeply upon the field, no complete survey of the ionization equilibria of these salts in anhydrous formic acid has been undertaken. Only a limited concentration range has been examined in each case, and it has been assumed that within this range the three salts, like those investigated by Schlesinger, behave as uni-univalent electrolytes.

Measurements were made in a cell of the Freas type with platinized electrodes. A 3-meter Leeds and Northrup bridge was employed. Alternating current (1000 cycles per sec.) was obtained by means of a constant-speed high-frequency generator; the telephone used was tuned to the same frequency. The experiments were performed in a Freas thermostat at  $25 \pm 0.01^\circ$ . The formic acid used possessed a specific conductivity of  $7.3$  to  $7.5 \times 10^{-6}$  mhos, a value somewhat higher than that obtained by Schlesinger and Martin.<sup>9</sup> The preparation of anhydrous acid and pure salts was carried out as described in a previous article. While no exceptional degree of accuracy is claimed for the results given below, they are probably in error by less than 0.5%.

<sup>7</sup> As dibasic organic acids do, in water solution, until ionization is very extensive.

<sup>8</sup> Any salt  $\text{RX}$  in its own acid  $\text{HX}$  possesses the characteristics of a base (see Schlesinger and Calvert, *This Journal*, 33, 1933 (1911); Kendall, Davidson and Adler, *ibid.*, 43, 1481 (1921)).

<sup>9</sup> Schlesinger and Martin, *ibid.*, 36, 1590 (1914).

In the following table,  $c$  denotes the concentration of the solution in gram equivalents per liter,  $\chi$  is the specific conductivity in reciprocal ohms (the specific conductivity of the solvent being directly subtracted),<sup>10</sup>  $\lambda$  is the equivalent conductivity,  $\lambda_0$  the equivalent conductivity at infinite dilution (extrapolated according to the method employed by Schlesinger<sup>11</sup> and  $k$  the ionization constant of the salt at 25°. It will be evident, from the paucity of the data, that the values given in the last two columns are somewhat uncertain. They are to be regarded, indeed, only as indicative of the relative strengths of the three electrolytes examined.

TABLE I.  
CONDUCTIVITIES OF FORMATES IN FORMIC ACID AT 25°.

Salt.	$c$ .	$\chi$ .	$\lambda$ .	$\lambda_0$ .	$k$ .
(H.COO) <sub>2</sub> Ba	0.0474	0.002575	55.59	60.3	0.515
	0.0923	0.004827	52.26		
	0.2758	0.001185	42.96		
(H.COO) <sub>2</sub> Mg	0.0479	0.001683	35.14	40.6	0.266
	0.0919	0.002931	31.90		
	0.0477	0.001295	27.15		
(H.COO) <sub>2</sub> Pb				35.2	0.124
	0.1047	0.002387	22.80		

It will be seen that the ionization constant of the barium salt is about twice as large as that of the magnesium salt, and more than four times as large as that of the lead salt.

We may now proceed to examine how compound formation varies with ionization throughout the series. In Table II below the ionization constants for the various salts and the addition compounds actually isolated from each system are listed. The last column shows the depression of the freezing point of the acid in solutions containing 5 mol % of dissolved salt.

IONIZATION AND COMPOUND FORMATION.		FORMATES IN FORMIC ACID SOLUTION.	
Salt.	Ionization constant, 25°.	Compounds isolated (A = salt; B = acid).	$\Delta T$ (5 mol % salt).°
H.COO.NH <sub>4</sub>	1.230	AB <sub>3</sub> ; AB	5.9
H.COOK	1.090	AB <sub>3</sub> ; AB <sub>2</sub> ; AB	6.6
H.COONa	0.810	AB <sub>2</sub> ; AB	5.9
H.COOLi	0.557	....	4.9
(H.COO) <sub>2</sub> Ba	0.515	AB	8.5
(H.COO) <sub>2</sub> Ca	0.422	....	insoluble
(H.COO) <sub>2</sub> Mg	0.266	....	insoluble
(H.COO) <sub>2</sub> Pb	0.124	....	insoluble

<sup>a</sup> The ideal freezing-point depression for formic acid containing 5 mol % solute is 3.3°.

<sup>10</sup> Following Schlesinger's procedure. The accuracy of this method is open to serious question (as discussed in the text later), but in any case the effect is here extremely small.

<sup>11</sup> Schlesinger and Mullinix, THIS JOURNAL, 41, 74 (1919).

The rule that ionization parallels compound formation in extent is evidently generally applicable throughout the series. The strongest bases each give several compounds, the weakest bases do not show a single sample of an isolable acid salt. Two minor discrepancies in the order of compound formation (potassium giving 3 compounds to 2 of ammonium, barium one to none of lithium) may plausibly be referred to changes in the order of basic strengths with temperature. The ionization constants tabulated refer to 25° while the compounds are isolated at much lower temperatures, and Schlesinger and Coleman<sup>12</sup> have found that the temperature coefficient of the ionization constant in certain cases is very large.

As has been pointed out previously,<sup>13</sup> however, compounds may be existent in a solution without making their appearance on the freezing-point diagram as stable solid phases. A more trustworthy method of establishing the relative extent of compound formation for the different formates in formic acid solution is fortunately available in the comparison of the depressions which they induce in the freezing point of the acid itself.<sup>14</sup> The ideal freezing-point depression curve for formic acid<sup>15</sup> and

Fig. 1.—Freezing-point depression curves. Formic acid as solvent. A=ideal curve; B=lithium formate; C=sodium formate; D=ammonium formate; E=potassium formate; F=barium formate.

<sup>12</sup> Schlesinger and Coleman, *THIS JOURNAL*, 38, 278 (1916).

<sup>13</sup> Kendall, Booge and Andrews, *ibid.*, 39, 2308 (1917).

<sup>14</sup> Compare Kendall and Booge, *ibid.*, 38, 1730 (1916).

<sup>15</sup>  $Q$  (the molar heat of fusion) is taken as 2420 cal. (Berthelot, *Compt. rend.*, 78, 716 (1874)).

the experimental curves obtained on addition of the various salts are shown in the accompanying diagram. The depressions for a single fixed concentration of salt (5 mol %) are also compared in Table II (p. 1848).

For the uni-univalent salts, the deviations from the ideal curve fall in the order  $K > (NH_4 \text{ or } Na) > Li$ , corresponding with the order of stability and complexity in compound formation. The extensive ionization of the salts in formic acid solution, of course, accounts for a great part of the abnormally large depressions obtained, but the data at the higher concentrations show clearly the additional effect of actual removal of solvent by compound formation. Thus the potassium salt gives twice the normal depression at 5 mol % concentration, while at 15 mol % the depression is nearly 4 times that calculated from the ideal curve. Compound formation in this case must be very extensive, as is evidenced not only by the compounds definitely isolated but by the transference-number data of Schlesinger and Bunting.<sup>16</sup> With the other uni-univalent salts the effect is appreciably smaller, particularly in the case of lithium. In view of the position of this metal at the head of the electrode potential series, indeed, the comparative weakness of its formate as a base and its corresponding inability to form isolable acid salts cannot be allowed to pass without comment, although no adequate explanation can be adduced at present.<sup>17</sup>

Of the 4 remaining salts of the type  $(H.COO)_2Me''$ , only those of barium and calcium are sufficiently soluble to give reliable comparable data. The freezing-point depression curve for the barium salt (see Curve F on the diagram; the calcium salt practically duplicates this curve up to 1.5 mol %) is more abnormal even than that for the potassium salt. Thus the observed depression for a solution of 5 mol % concentration is  $8.5^\circ$ , compared with a calculated value of  $3.3^\circ$ . In view of this, it appears very improbable that Schlesinger's assumption that the alkaline earth formates behave, in moderately concentrated solutions, as uni-univalent electrolytes can be valid, since only by assuming a compound of truly enormous complexity could the position of the barium curve be accounted for on this basis. If we admit that the salt can give 3 ions by dissociation, however, the observed depressions are just about what might be expected.

#### Systems of the Type Sulfuric Acid : Metal Sulfate.

The same experimental procedure was employed as in the case of formic acid systems, except that sulfuric acid of minimum conductivity was made up directly in the cell (by gradual addition of acid slightly under 100%

<sup>16</sup> Schlesinger and Bunting, *THIS JOURNAL*, 41, 1934 (1919).

<sup>17</sup> The question will be taken up in a later article, in connection with the atomic volume factor.

to acid slightly over 100%) in order to avoid contamination with atmospheric moisture during transfer. The specific conductivity of the acid so prepared varied from 0.01035 to 0.01050 reciprocal ohm at 25°. Lichty<sup>18</sup> in a very careful investigation, obtained the value 0.01041; according to his conductivity-composition data, the acid here used contained less than 0.005 % of water.

The conductivity results for a series of sulfates at a single fixed concentration (0.04 gram equivalents per liter) in the 100% acid are presented in Table III below. In the preparation of this table, the method adopted by previous investigators for the evaluation of the specific conductivity of the salt has been followed, the specific conductivity of the pure solvent being subtracted directly from that of the solution.

TABLE III.  
CONDUCTIVITIES OF SULFATES IN SULFURIC ACID AT 25°.

Salt.	Solution.	Specific conductivity		Equiv. cond. of salt.
		Solvent.	Due to salt.	
Na <sub>2</sub> SO <sub>4</sub>	0.01206	0.01044	0.00162	40.5

CaSO <sub>4</sub>	0.01210	0.01043	0.00167	41.8
MgSO <sub>4</sub>	0.01130	0.01043	0.00087	21.8
ZnSO <sub>4</sub>	0.01207	0.01039	0.00168	42.0
PbSO <sub>4</sub>	0.01237	0.01050	0.00187	46.8
Ag <sub>2</sub> SO <sub>4</sub>	0.01208	0.01035	0.00173	43.3

Previous measurements upon the conductivities of neutral sulfates in 100% sulfuric acid have been carried out by Walden,<sup>19</sup> Hantzsch,<sup>20</sup> Bergius<sup>21</sup> and Poma.<sup>22</sup> The results obtained are extremely discordant; thus for sodium sulfate at the concentration examined above the interpolated equivalent conductivity values of these 4 observers are 97, 31, 46 and 14, respectively. From results of this order of accuracy, it is obviously futile to attempt to draw any conclusions.

The main source of error is undoubtedly due to the solvent correction, which varies from 80 to 90% of the total conductivity. A small error in this correction will introduce a very significant error in the equivalent conductivity of the salt, and the tacit assumption that the specific conductivity of the pure solvent is unchanged on addition of neutral salt is quite as unjustified as would be the corresponding assumption that the ionization equilibrium of water is unaffected by addition of a base. If we knew the mobilities of the various ions existent in any given solution, it might be possible for us to apply more dependable solvent corrections,<sup>23</sup>

<sup>18</sup> Lichty, *THIS JOURNAL*, 30, 1841 (1908).

<sup>19</sup> Walden, *Z. anorg. Chem.*, 29, 383 (1902).

<sup>20</sup> Hantzsch, *Z. physik. Chem.*, 61, 293 (1908).

<sup>21</sup> Bergius, *ibid.*, 72, 338 (1910).

<sup>22</sup> Poma, *J. chim. phys.*, 10, 187 (1912).

<sup>23</sup> Compare Kendall, *THIS JOURNAL*, 39, 7 (1917).

but at the present time we cannot do more than concede that all of the salts investigated give conductivity values indicating approximately the same degree of ionization at the concentration here studied. To deduce differences in the basic ionization constants of sulfates in sulfuric acid from the different equivalent conductivities given in the last column of Table III above would obviously be quite unwarranted. It may be noted here that differences in the extent of acid salt formation are also less pronounced in the sulfuric acid than in the formic acid series.<sup>5</sup>

In the third series for which data are available, however, (namely systems of the type water:metal hydroxide) differences in basic ionization constants and in the stability and complexity of hydrates are exceedingly great. At the head of the electrode potential series we have the strongest bases, the alkali hydroxides, each of which gives several stable hydrates. The hydroxides of all metals in the neighborhood of hydrogen are scarcely ionized at all in aqueous solution. At the foot of the series we find an increase in basic strength again becoming apparent, silver hydroxide being a moderately strong base. Solubility variations are similarly much more marked among the hydroxides than in either the formate or the sulfate series.<sup>24</sup>

From the results of this and previous articles it may be concluded, therefore, that systems of the general type  $HX : RX$  supply strong support for the fundamental relationships suggested between diversity of chemical character (*i. e.*, electrode potential difference between R and H), compound formation, solubility and ionization. Variations in all of these properties, however, and particularly variations in ionization, can be much more clearly traced when X is a weakly acidic radical. With hydroxides enormous differences are evident, with formates the gradations are much less steep (for example, the ionization constant of the potassium salt is only 9 times that of the lead salt), with sulfates the solvent correction error is sufficient to mask any differences in ionization entirely. The examination of intermediate series (such as cyanides, acetates or fluorides) would undoubtedly add results of great interest in this connection, but must be deferred for the present in favor of work on systems of other types.

### Summary.

Conductivity measurements have been carried out for neutral formates in formic acid solution and for neutral sulfates in sulfuric acid solution. In the case of the formates, it has been possible to obtain direct confirmation for the parallelism between the extent of compound formation and ionization. For the sulfates, however, the uncertainty of the solvent correction is so great as to obscure the results.

<sup>24</sup> Compare Kendall, Davidson and Adler, *THIS JOURNAL*, 43, 1490 (1921).

Variations in compound formation, solubility and ionization in systems of the general type  $HX : RX$  are all, indeed, more extreme the weaker the acidic radical  $X$ . Hydroxides in water differ more widely than formates in formic acid, these again are more diverse than sulfates in sulfuric acid.

## COMPOUND FORMATION IN PHENOL : CRESOL MIXTURES.

BY JAMES KENDALL AND J. J. BEAVER.

Received June 6, 1921.

It has been shown in previous articles<sup>1</sup> that the extent of addition compound formation in binary liquid mixtures is controlled primarily by "chemical contrast," the stability of complexes increasing uniformly with the differences in character (*i. e.*, in the positive or negative nature of the constituent groups) of the two components. A great number of systems of very diverse types have been carefully examined, and incidentally no fewer than 101 new compounds have been discovered. To all of these systems the simple generalization given above is directly applicable, except to systems containing phenols.

Several times in the course of the work<sup>2</sup> abnormal results with phenols have been noted and tentative explanations, such as the existence of phenol in two tautomeric forms of widely different acidic strengths, proposed. Recently, Dawson and Mountford<sup>3</sup> have made a thorough investigation of compound formation in systems of the type phenol: cresol by the freezing-point method, obtaining definite compounds in 5 out of 6 cases. This they considered as rather remarkable in view of the close chemical similarity of the components, and concluded that "the relations disclosed by the freezing-point diagrams are consequently not in accord with what should have been anticipated on the basis of the views advocated by Kendall." The fact that the uniform abnormality of the phenols had already been emphasized was apparently overlooked.

A similar study of phenol: cresol systems by Fox and Barker<sup>4</sup> leads to quite contradictory results, a stable compound being isolated in only one of the six mixtures examined. This discrepancy is in all probability due to inadequate purification of the materials employed by Fox and Barker, and to the general inferiority of their method. In view of the extreme care exercised by Dawson and Mountford in all details, there is no reason

<sup>1</sup> For a summary of results and conclusions, see Kendall, Booge and Andrews, *THIS JOURNAL*, 39, 2304 (1917).

<sup>2</sup> Kendall, *ibid.*, 36, 1241 (1914); 38, 1317 (1916); Kendall, Booge and Andrews, *loc. cit.*, p. 2306.

to doubt the accuracy of their freezing-point data. The fact established by Fox and Barker, however, that the boiling-point curves of phenol-cresol mixtures show very little departure from the linear, is not what would be expected from systems in which addition compounds are present in appreciable quantity.

The present paper gives the results of further investigations on the physico-chemical properties of phenol-cresol mixtures, undertaken in the hope either of bringing these systems into line with the rest, or of obtaining some clue to the source of the abnormalities which they exhibit.

### Conductivity Measurements.

Kendall and Gross have demonstrated, in a recent article,<sup>5</sup> the validity of the general rule that compound formation and ionization in solutions proceed in parallel. For several series of binary organic mixtures it has been established experimentally that an increase in compound formation is regularly accompanied by a similar increase in specific conductivity. Where the extent of compound formation was known to be minute, the conductivity was almost immeasurable; as compound formation increased in amount, the conductivity became appreciable; where combination was extensive, the conductivity was very markedly increased.

As the first line of attack in the present work, it was consequently decided to determine the specific conductivity-composition curves of phenol-cresol mixtures. The essential principles of the experimental method employed have already been described by Kendall and Gross. The specific conductivities of the pure substances and solutions here under examination proved to be so extremely small, however, that some additional refinements in technique were necessary in order to obtain the required degree of accuracy in the experimental results.

**Conductivity Apparatus.**—The cell finally adopted was a 6-cylinder cell of the Beans and Eastlack type,<sup>6</sup> with a constant of 0.001426. The electrodes consisted of concentric platinum cylinders, 1 mm. apart, sand-blasted and connected alternately. With this cell it was possible to obtain very satisfactory sound minima with solutions of conductivity  $1.0 \times 10^{-9}$  mhos. Platinized electrodes could not be used, since in the presence of platinum black phenol-cresol solutions rapidly turn yellow, with a measurable increase in conductivity.

The bridge employed was a 4.70-meter circular slide-wire instrument, well-grounded and carefully calibrated. The resistance coils, up to 1000 ohms, were bifilar wound; those over 1000 ohms were of the Curtis type. A Vreeland oscillator gave a pure sine-wave alternating current of 1000 cycles per second. A high-resistance telephone receiver was used. The capacity of the cell was balanced out by means of a rotary air condenser connected in parallel with the resistance coils.

Most of the measurements were carried out in a large Freas thermostat, regulated to  $25^{\circ} \pm 0.005^{\circ}$ . Many of the solutions which normally

<sup>5</sup> Kendall and Gross, *THIS JOURNAL*, 43, 1426 (1921).

<sup>6</sup> Beans and Eastlack, *ibid.*, 37, 2674 (1915).

freeze at a higher temperature could be supercooled sufficiently to enable direct determinations at  $25^{\circ}$  to be made. With pure phenol and mixtures very rich in phenol, however, solidification could not be prevented in the presence of the sand-blasted electrodes, although viscosity measurements at  $25^{\circ}$  were later successfully accomplished. To complete the specific conductivity curves for phenol-cresol mixtures at  $25^{\circ}$  it was therefore necessary to perform experiments for these concentrations at higher temperatures and extrapolate the results.<sup>7</sup> For this purpose 2 smaller thermostats, regulated to  $40^{\circ} \pm 0.05^{\circ}$  and  $50^{\circ} \pm 0.10^{\circ}$ , respectively, were fitted up. Linear extrapolation was assumed to be valid over the small temperature range involved.<sup>8</sup> While this assumption is probably not strictly accurate, the values so obtained exhibit very good agreement with the direct measurements at  $25^{\circ}$ , as may be seen by referring to Fig. 1. In this diagram, the extrapolated sections of the various curves are indicated by broken lines.

Mixtures were made up by direct weighing, with the use of a Lunge pipet. The compositions as given in the tables below are accurate to within  $\pm 0.05\%$ . The specific conductivity data themselves possess a *relative* accuracy of the order of  $0.1\%$ , but owing to the impossibility of compensating exactly for inductance and capacity effects under the conditions of experiment, no claim is made for so high a degree of accuracy in their *absolute* values.

**Purification of Materials.**—As in the work of Kendall and Gross, it was found that the presence of impurities in quantities insufficient to exert any appreciable influence upon the freezing point or boiling point frequently involved a very considerable change in specific conductivity. A constant specific conductivity was therefore made the final criterion of purity.

In the case of each substance used, the purest material obtainable was repeatedly fractionated from special stills of Pyrex glass.<sup>9</sup> A middle fraction of constant freezing point usually gave a product of constant specific conductivity after 3 to 6 additional fractionations. In view of the hygroscopic nature of the materials under study and of the marked influence exerted by traces of water upon their specific conductivities, the last fractionations and conductivity determinations were restricted entirely to cold, dry days. The sensitivity of the materials towards moisture undoubtedly constitutes the chief source of error in the whole of the experimental work, and all possible precautions were taken to minimize its effect upon the results.

<sup>7</sup> Compare Kendall and Gross, *THIS JOURNAL*, 43, 1428 (1921).

<sup>8</sup> Compare Kendall and Brakeley, *ibid.*, 43, 1830 (1921).

<sup>9</sup> It was found that addition of a small quantity of anhydrous powdered sodium carbonate was very beneficial in accelerating the elimination of impurities.

**The System Phenol: *o*-Cresol.**—A c. p. sample of phenol, after about 20 fractional distillations, gave a final product of specific conductivity  $11.98 \times 10^{-8}$  at  $40^\circ$  and  $14.07 \times 10^{-8}$  at  $50^\circ$ . The only previously recorded value is that of Riesenfeld,<sup>10</sup>  $43 \times 10^{-8}$  at  $43^\circ$ . The freezing point obtained with our material was  $39.70^\circ \pm 0.02^\circ$ , identical with that found by Morgan and Egloff<sup>11</sup> for a specially prepared and purified sample. Several investigators have reported considerably higher values for unpurified specimens of phenol,<sup>12</sup> which would appear to indicate that commercial phenol is apt to contain an impurity which raises its fusion point. The original material here employed, indeed, gave a freezing point higher than that of the final product.

Pure *o*-cresol was obtained from a c. p. product by similar continued fractionation, the final material possessing a specific conductivity of  $0.127 \times 10^{-8}$  at  $25^\circ$  and a freezing point of  $30.60^\circ \pm 0.02^\circ$ . No previous measurements of the conductivity have been made; for the freezing point the most reliable recorded value<sup>3</sup> is  $30.45^\circ$ .

The conductivity results for the various mixtures examined at  $25^\circ$  are presented in Table I. The compositions of the solutions are expressed in molecular percentages throughout. The viscosity data which are appended will be discussed later.

TABLE I.

PHENOL: <i>o</i> -CRESOL.					
Mol. % phenol.	Spec. cond. $\times 10^8$ .	Viscosity.	Mol. % phenol.	Spec. cond. $\times 10^8$ .	Viscosity.

45.02	2.988	0.1070	100.00	8.84	0.08945
51.74	3.379	0.1040			

**The System Phenol: *p*-Cresol.**—The preparation of pure *p*-cresol from several standard c. p. samples was unsuccessfully attempted, the elimination of traces of *m*-cresol (which possesses almost exactly the same boiling point)<sup>14</sup> not being possible. Finally a satisfactory product was obtained by diazotizing pure *p*-toluidine<sup>15</sup> (f. p., 43.0°), distilling with steam, extracting the distillate with ether, and drying and fractionating the extract as described above. The specific conductivity of the final material was  $1.378 \times 10^{-8}$  at 25°; it gave a freezing point of  $34.55 \pm 0.02^\circ$ . Practically the same freezing-point value was obtained in previous researches of this series;<sup>13,12</sup> Dawson and Mountford, in their work, used a sample with f. p. 34.15°. No previous determinations of specific conductivity are recorded in the literature.

*p*-Cresol was found to be much more sensitive to light than its homologs, even a carefully purified specimen turning yellow in the course of a day if kept exposed. The data here presented were obtained with the use of freshly prepared material throughout.

**Systems containing Two Cresols.**—In Tables IV to VI (p. 1858), the conductivity and viscosity results for binary cresol mixtures are given.

<sup>14</sup> The b. p. (under 760 mm. pressure) of *m*-cresol is 202.1°, of *p*-cresol, 202.5°. In the cases of phenol and *p*-cresol, the differences in b. p. are sufficient to permit of systematic fractionation (see Dawson and Mountford, *J. Chem. Soc.*, 113, 937 (1918)).

<sup>15</sup> The reaction was carried out in 6 molar HCl solution by slow addition of the theoretical amount of sodium nitrite, the temperature being maintained below 10° and rapid admixture being ensured by vigorous stirring. When the reaction was complete the temperature was very gradually raised to 40° and the solution allowed to stand overnight before distilling with steam.

The specific conductivity results given in the above tables are represented graphically in Fig. 1. Curves I to III show the data for mixtures of phenol with the cresols, Curves IV to VI the data for binary cresol mixtures.

It will be immediately evident, from inspection of this diagram, that the specific conductivities of all of the solutions examined are very little

Fig. 1.—Specific conductivity-composition curves.

different from those of the pure components.<sup>16</sup> This type of curve, according to the predictions of Kendall and Gross,<sup>17</sup> is characteristic of all mixtures in which the two components are essentially similar in character. In such mixtures little or no increase in molecular complexity through compound formation is to be expected. Hence the observed conductivity of any solution should not differ significantly (if the parallelism between molecular complexity and ionization is accepted) from that obtained by linear extrapolation from the specific conductivities of its components.

The conductivity results here obtained are therefore in apparent contradiction with the freezing-point results of Dawson and Mountford, and in agreement with the generalizations formulated in previous papers of this series. This discrepancy will be discussed more fully below, after the work on some other physical properties of phenol-cresol mixtures has been described. The investigation of the viscosity-composition curves of these systems was chosen as the second line of attack in the present work, in view of the marked effect of changes in molecular complexity upon the viscosity.

### Viscosity Measurements.

Viscosity curves for binary liquid mixtures fall, in general, into three distinct types.<sup>18</sup> The ideal curve, given by solutions in which no interactions at all take place on mixtures of the components, is not linear but appreciably sagged. Where compound formation occurs on admixture, the viscosity (owing to the production of more viscous complexes) is abnormally high; if compound formation is extensive the curve may even exhibit a *maximum*. Where disassociation of an associated component takes place on admixture, the viscosity (owing to the production of less viscous molecules) is abnormally low; if disassociation is extensive the curve may even exhibit a *minimum*. In certain cases both compound formation and disassociation effects may be existent, producing a curve of a "pseudo-ideal" type.<sup>19</sup> A brief consideration of the chemical character of the components will suffice, however, to enable us to distinguish such a system from one which is truly ideal. Usually, also, one effect will predominate sufficiently to give a curve quite distinct from the normal type.

It was hoped, therefore, that a study of the viscosity curves of phenol:cresol systems would either make possible a decision between the apparently conflicting conclusions drawn from freezing-point and conductivity measurements, or indicate a means of reconciliation.

<sup>16</sup> The curve for the system *m*-cresol : *p*-cresol differs slightly from the 5 others, exhibiting an exceedingly small flat maximum, but in view of the extremely small conductivities given by this system throughout, no special significance is attached to this fact.

<sup>17</sup> Kendall and Gross, *THIS JOURNAL*, **43**, 1420 (1921).

<sup>18</sup> See Kendall and Monroe, *ibid.*, **43**, 115 (1921).

<sup>19</sup> Compare Kendall and Brakeley, *ibid.*, **43**, 1831 (1921).

The apparatus used for the determination of viscosities was of the Bingham type,<sup>20</sup> the experimental procedure being essentially as described in previous work.<sup>21</sup>

Very extensive investigations have recently been carried out by Bramley<sup>22</sup> on the viscosity of systems of the general type phenol : aniline. The viscosities and densities obtained by us for phenol and the cresols may be compared with the results of Bramley by reference to the following table. Density data by Dawson and Mountford are also included.

	Phenol.	o-Cresol.	m-Cresol.	p-Cresol.
$\eta_{25^\circ}$ (Bramley).....	0.0883	0.07620	0.1240	0.1413
(Kendall and Beaver).....	0.08945	0.07608	0.1342	0.1474
$d_4^{25}$ (Bramley) .....	1.0710	1.0440	1.0293	1.029
(D. and M.) .....	1.0710	1.0415	1.0295	1.0295
(K. and B.) .....	1.0708	1.0414	1.0298	1.0295

It will be seen that the agreement is not all that could be expected in every case. In view, however, of the extremely careful methods of purification employed in the present work, we believe our values to be more reliable.

The relative accuracy of the viscosity data presented in Tables I to VI above is  $\pm 0.2\%$ . With the apparatus employed, a somewhat higher degree of precision is attainable for most substances, but the temperature coefficient of viscosity of the liquids here examined is extremely high, approximately 10% per degree.<sup>22</sup> Very accurate density determinations are not necessary for the evaluation of viscosities with the Bingham type of instrument.<sup>23</sup> Consequently, after it had been found for each system that the density of an approximately equimolecular mixture was, within error limits, identical with that calculated from the densities of its components, it was assumed that no appreciable contraction occurred on admixture in any case,<sup>24</sup> and the densities for the remaining solutions were obtained by linear interpolation from the specific volume-weight composition curves.

The viscosity results for the 6 systems are reproduced in graphic form in the accompanying diagram Fig. 2. From inspection of the curves, it is again immediately evident that no appreciable change in average molecular complexity occurs on admixture in any system. The curves are apparently very near to the ideal type.

<sup>20</sup> Bingham, *J. Ind. Eng. Chem.*, 6, 233 (1914); Bingham, Schlesinger and Coleman, *THIS JOURNAL*, 38, 27 (1916).

<sup>21</sup> Kendall and Monroe, *ibid.*, 39, 1787 (1917).

<sup>22</sup> Bramley, *J. Chem. Soc.*, 109, 434 (1916).

<sup>23</sup> The density enters into the working formula only in a correction factor (approximately 1% of the total).

<sup>24</sup> This assumption is in agreement with the actual density determinations carried out by Fox and Barker (*J. Soc. Chem. Ind.*, 36, 845 (1917)) with less pure materials.

When it is remembered, however, that we have independent evidence from other physical properties<sup>25</sup> that phenol and the cresols are highly

Fig. 2.—Viscosity-composition curves.

associated liquids in the pure state, it follows that this approximation to the normal type of curve must be due to the mutual compensation of the two opposing effects discussed above—compound formation and disassociation. Neither effect is here predominant; combination between the compounds appears to be practically counterbalanced by mutual depolymerization, leaving the average molecular complexity substantially unchanged.

To obtain confirmation of this point of view, a third line of attack was formulated, namely, the determination of the molecular weights of the pure substances, and the average molecular weights of certain of their binary mixtures, in an inert solvent.

### Molecular Weight Determinations.

The freezing point of a pure liquid, on addition of an ideal solute, will be depressed according to the equation<sup>26</sup>  $\ln x = (-Q/RT_o) \cdot (\Delta T/T)$  (where  $x$  is the mol fraction of solvent in the solution,  $Q$  the mol heat of fusion of the solvent,  $T_o$  and  $T$  the absolute freezing points of the pure solvent and the solution respectively,  $\Delta T$  the freezing-point depression, and  $R$ , 1.9852). If the solute is not ideal but associated, its average molecular weight in any solution of known composition can be calculated from the above equation<sup>27</sup> by substituting the experimentally determined value for  $\Delta T$  and solving for  $x$ .

<sup>25</sup> See Turner, "Molecular Association," 1915; also references in text later.

<sup>26</sup> Roozeboom, "Heterogene Gleichgewichte," 2, 273 (1904).

<sup>27</sup> Compare Washburn and Read, *THIS JOURNAL*, 41, 729 (1919). The error involved in the application of the simpler Raoult equation to the determination of molecular weights at high concentrations of solute is quite considerable.

As a suitable solvent, benzene was selected. The ideal freezing-point depression curve for this liquid has already been indicated in a previous article.<sup>21</sup> The benzene employed in the present work was very carefully prepared by repeated fractionation of a thiophene-free sample, dried over sodium. It possessed, within error limits, the same physical constants as noted in the preceding reference.

To determine the freezing-point depression of benzene on addition of phenol and its homologs the standard Beckmann apparatus and method were used. The thermometer was calibrated at the Bureau of Standards. Supercooling was limited to between 0.1° and 0.2°. For the depressions tabulated below the accuracy claimed is about 0.01°.

The positions of three of the resultant freezing-point depression curves (those for phenol, for *o*-cresol, and for an equimolecular mixture of phenol and *o*-cresol) with respect to the ideal are shown in Fig. 3. Phenol is evidently far from being monomolecular in benzene solution, the abnormally small depressions obtained pointing towards very extensive association. The curve for *o*-cresol, on the other hand, is very much closer to the ideal curve, indicating that this substance is far less highly associated in benzene solution.<sup>28</sup> The equimolecular mixture, finally, gives

<sup>29</sup> Hildebrand, (THIS JOURNAL, 38, 1452 (1916)) has shown that it is dangerous to ascribe deviations from the ideal curve to differences in molecular complexity when the solutes possess very divergent internal pressures. In view of the essential similarity in character of phenol and the cresols, however, the comparisons here made between

a curve which falls almost exactly midway between those of its two components. In other words, the average molecular complexity is practically unchanged by admixture.

Fig. 3.—Freezing-point depression curves in benzene.

Precisely the same behavior is exhibited by the remaining results presented in Table VII (p. 1862). Each of the two mixtures tested (phenol and *m*-cresol in molecular proportions 1 to 2; *o*-cresol and *p*-cresol in the molecular proportions 1 to 2) corresponds to a definite compound isolated by Dawson and Mountford. The freezing-point depression curve in each case is found to occupy a position intermediate between the curves of the respective components, and nearer to that component which is present in excess.

If these phenol-cresol compounds were true *addition compounds* (their formation involving an increase in molecular complexity) entirely different results would have been obtained. Even although dissociation of such compounds into their simpler components would be greatly favored by the dilution of the mixture with a large excess of solvent benzene, we should still find appreciable combination indicated by abnormally small freezing-point depressions. Thus, to cite an instance, which will be taken up in detail in a subsequent communication, the freezing point of a solution of ethyl acetate in benzene is practically unchanged on addition of an equimolecular amount of trichloro-acetic acid,<sup>29</sup> showing that the acid-ester addition compound formed is only very slightly broken up into its components in benzene solution. A similar, but much less decided in their association factors are valid, even although the absolute values, as given later, may not be altogether correct.

<sup>29</sup> In a previous article (Kendall and Booge, *THIS JOURNAL*, 38, 1712 (1916)) it has been shown that these two substances form a stable equimolecular addition compound, melting at  $-27.5^{\circ}$ .

crease in molecular complexity on admixture in benzene solution is exhibited by ethyl acetate and acetic acid. In the cases here studied, however, the freezing-point depression curves resemble the viscosity curves in indicating that hardly any change in average molecular complexity occurs in phenol-cresol mixtures; any compound formation between the components must therefore be compensated for by simultaneous depolymerization

In order to obtain a definite idea with regard to the relative molecular complexities in the different solutions examined in this article, the following table may be consulted. As an arbitrary fixed concentration for comparing the various systems, 5 mol % solute has been selected. Specific-conductivity and viscosity data are added for convenience of reference in the subsequent discussion.

TABLE VIII.  
ASSOCIATION OF PHENOL, ETC., IN BENZENE SOLUTION.  
(Solute concentration = 5 mol %.)

	$\Delta T$ .	Mol. Wt.	Average mol. complexity.	Spec. cond. $\times 10^8$ , 25°.	Viscosity 25°.
Phenol .....	1.780	178.4	1.897	8.84	0.08945
<i>o</i> -Cresol .....	2.861	125.1	1.157	0.127	0.07608
<i>m</i> -Cresol .....	2.450	146.9	1.358	1.397	0.1342
<i>p</i> -Cresol .....	2.400	150.2	1.390	1.378	0.1474
1 Phenol + 1 <i>o</i> -Cresol	2.342	144.5	1.427	0.979	0.08415
1 Phenol + 2 <i>m</i> -Cresol	2.258	153.2	1.482	2.230	0.1121
1 <i>o</i> -Cresol + 2 <i>p</i> -Cresol	2.613	137.6	1.274	0.570	0.1177

The results are in good agreement with those of previous investigators<sup>30</sup> in indicating that phenol is much more highly associated than the cresols. The specific conductivity of phenol, it will be noted, is also considerably greater than the values obtained for the cresols, a point in exact accordance with the work of Kendall and Gross<sup>31</sup> in which a parallelism between specific conductivity and molecular complexity in a series of liquids of similar type was predicted.

*o*-Cresol is much less associated than its two isomers, all of the physical properties of which are strikingly similar. In line with this, the specific conductivities of *m*-cresol and *p*-cresol are much higher than that for *o*-cresol. The influence of a larger association factor is also evident in the relative viscosity values.

With regard to the behavior of the three binary mixtures tested, nothing needs to be added here to what has been said in the discussion above.

<sup>31</sup> Kendall and Gross, *THIS JOURNAL*, **43**, 1418 (1921).

### General Conclusions.

The following experimental facts have been established with regard to phenol-cresol mixtures: (a) 5 out of 6 of the possible binary systems give isolable compounds by the freezing-point method; (b) no significant changes in specific conductivity occur on admixture in any case; (c) the viscosity-composition curves are all "pseudo-ideal" in type; (d) the freezing-point depression curves given by binary mixtures in benzene solution are intermediate between the curves found for the pure components. The conclusions drawn from these several facts are not all in harmony with one another, as has been remarked upon at various places in the text above. It remains for us to examine whether a rational reconciliation can be effected now between the various results and the general hypothesis correlating chemical contrast, compound formation and conductivity in solutions developed in previous articles of this series, or whether the whole behavior of systems containing phenols must continue to be classed as "abnormal."

On careful consideration of the problem, it appears that an extension to these solutions of the views presented by Kendall and Gross<sup>32</sup> regarding conductivity and molecular complexity in pure associated liquids and in binary mixtures of the same supplies a complete explanation of all the points in dispute.

Phenol and its homologs, as already shown, are highly associated in the liquid state. The association of phenol, in particular, has been critically investigated by Yamanoto,<sup>33</sup> the conclusion reached being that the main equilibrium is represented by the equation,

Determinations of the molecular weight of phenol in various organic solvents by other workers, however, indicate that still more complex molecular types are also existent. The attractive forces between simple molecules, inducing the formation of larger molecular aggregates in the liquid, must consequently be very pronounced; in other words, the substance is markedly "polar." The same applies, to somewhat less degree, to the three cresols.

Now it has been noted by Kendall and Gross that in a solution containing two highly associated components of similar character, compounds of the general type  $(\text{AB})_x(\text{CD})_y$  are undoubtedly formed in quantity. The average molecular complexity of such a mixture, however, (and hence its specific conductivity also) will not differ greatly from that of its pure components, since extensive disassociation of these is also involved. The complexes here existent are to be regarded, indeed, not as *addition* but

<sup>32</sup> Kendall and Gross, *THIS JOURNAL*, 43, 1420 (1921).

<sup>33</sup> Yamanoto, *Sakurai Memorial Papers*, No. 12, p. 33 (1908).

rather as *substitution* compounds, for disintegration and recombination of the various molecular and ionic types present will evidently result, finally, in an almost "haphazard" replacement of the different radicals by one another at all points of the original associated molecules. If the attractive forces between the constituent groups are such that a certain particular substitution complex predominates in stability, then it is only logical to expect that such a complex may be definitely isolated under suitable conditions. (*e. g.*, by freezing the solution.) The phenol-cresol compounds discovered by Dawson and Mountford are consequently not true addition compounds (as, indeed, the physical properties investigated in this article have sufficiently demonstrated) but substitution compounds formed by the replacement of part of an associated molecule by a homolog. It is very significant in this connection that *all* of the five compounds isolated by Dawson and Mountford are trimolecular, *e. g.*, 1 phenol + 2 *m*-cresol. Such complexes could evidently be readily formed from the predominating phenol complex  $(C_6H_5OH)_3$  by replacement of two phenol groups. No increase in the average molecular complexity of the mixture is involved in such replacements, and the apparent contradiction between Dawson and Mountford's results and those of the present work is therefore entirely removed.

It must also be noted that mixtures of this type, if no particular substitution complex predominates in stability, will necessarily tend to give "mixed crystals" on solidification. This is here the case with one system only, phenol:*o*-cresol. A careful determination of the solidus curves would indicate, in all probability, limited formation of solid solutions in the remaining systems. Precisely analogous behavior is shown by binary mixtures of fused salts of similar character, *e. g.*, neutral salts of the alkali metals.<sup>34</sup> Thus potassium sulfate gives a continuous series of solid solutions with sodium sulfate and with potassium chromate. Lithium sulfate and potassium fluoride, on the other hand, form stable equimolecular compounds with potassium sulfate. These latter systems are evidently identical in character with the five compound-producing phenol-cresol mixtures here examined.

### Summary.

By repeated fractionation, very pure samples of phenol and the three cresols have been prepared, and their chief physical constants determined. The specific conductivity and viscosity curves for phenol-cresol mixtures have been carefully investigated; freezing-point depression curves for phenol, the cresols, and various binary mixtures in benzene solution have also been constructed. Without exception, the results indicate that no increase in molecular complexity occurs on admixture. This is in agree-

<sup>34</sup> Landolt-Börnstein, "Tabellen," 1912, p. 611-87.

ment with the views correlating addition compound formation with diversity in character of the components developed in previous articles of this series. It is apparently in disagreement, however, with the fact that Dawson and Mountford succeeded in isolating definite compounds from phenol-cresol mixtures in five out of six systems.

A brief consideration of the equilibria existent in binary mixtures of associated liquids has shown that the compounds obtained by Dawson and Mountford are to be regarded as substitution rather than as addition compounds. Under this view, no conflict exists between the results of Dawson and Mountford and those of the present work; both fall directly into line with the general theory.

## SOME PHYSICAL PROPERTIES OF AQUEOUS SOLUTIONS OF CERTAIN PYRIDINE BASES.

BY WILLIAM JACOB JONES AND JOHN BAMBER SPEAKMAN.

Received June 8, 1921.

The physical properties of mixtures of pyridine and water have been the subject of a number of investigations.<sup>1</sup> The optical and thermal constants of pyridine and the mono methylpyridines have been determined by Constam and White.<sup>2</sup> More aqueous solutions of the higher homologs of pyridine have not been examined up to the present with the exception of 3 and 4 methylpyridines and 2,6-dimethylpyridine, studied by Flaschner.<sup>3</sup> In the present article are given measurements of densities and other physical characteristics of aqueous solutions of some of these higher homologs.

### Preparation of Materials.

The bases used had been purified by the methods described elsewhere.<sup>4</sup> On account of their hygroscopicity they were redistilled before use from solid sodium hydroxide, in an apparatus previously dried by the passage of air dried with sulfuric acid, and the receiver was protected from the external air by a calcium chloride tube. They were then preserved in desiccators kept in the dark. The aqueous solutions were made up by weight with conductivity water in the type of weighing bottle recommended by Hartley, Thomas and Applebey, having its stopper fitting over the outside of the neck.

## Densities.

It was originally intended to employ the determinations of the densities of aqueous solutions of pyridine made by Hartley, Thomas and Applebey,<sup>1</sup> for the purpose of finding the composition of the constant-boiling mixture. Since a different value for the density of anhydrous pyridine was found, it was necessary for our needs to redetermine the densities. Freshly distilled samples were used. Our values are corrected for air displacement and are here tabulated. The table also embodies the results obtained by us for 2- and 3-methylpyridines.

TABLE I.  
DENSITIES.

Water. %	Pyridine. $d_4^{20}$	2-Methylpyridine. $d_4^{20}$	3-Methylpyridine. $d_4^{20}$
0	0.9776	0.9404	0.9515
10	0.9888	0.9637	0.9675

## Compositions of the Constant-boiling Mixtures.

Goldschmidt and Constam<sup>1</sup> who were the first to prepare the constant-boiling mixture in the case of aqueous pyridine, concluded that it was an undissociated compound,  $C_5H_5N \cdot 3H_2O$ , basing their conclusions on its nitrogen content and its vapor density, which they gave as 1.19 to 1.16, referred to air. This value of the vapor density, however, corresponds with complete dissociation, and the accuracy of the value given by them is borne out by our experiments, in which the Victor Meyer method was used. The vapor density of the constant-boiling mixture of 2-methylpyridine and water also corresponds with complete dissociation.

We have also undertaken determinations by the cryoscopic method of the molecular weights of the bases in aqueous solution. For this purpose we prepared standard aqueous solutions of pyridine and of 2-methylpyridine by adding known weights of the constant-boiling mixtures to known weights of water. In solutions containing less than 4% of the bases the molecular weights obtained are those of the bases, namely, 79 and 93 respectively. With 6% solutions our results indicate that, if it may be assumed that we are still dealing with dilute solutions, either there is polymerization of the base, which is improbable, or there is partial conversion into hydrate.

# Variation of the Composition of the Constant-boiling Mixtures with Pressure.

The method of investigation here employed was that of Roscoe.<sup>5</sup> Our results were as follows:

TABLE II.  
VARIATION OF COMPOSITION OF CONSTANT-BOILING MIXTURES WITH THE PRESSURE.

Pressure. Mm. Hg.	Boiling point. °C.	Density of distillation. $d_4^{25}$
Pyridine.		
767.0	93.0	1.00315
633.5	87.7	1.00313
483.0	80.8	1.00311
358.5	73.7	1.00316
235.5	64.2	1.00316
2-Methylpyridine.		
753.0	93.5	0.99318
653.0	89.5	0.99318
572.5	86.4	0.99318
401.5	77.5	0.99318
194.0	61.5	0.99320
3-Methylpyridine.		
768.0	96.2	0.99247
596.0	89.6	0.99255
450.0	82.2	.....
425.5	80.8	0.99259
270.0	70.0	0.99276

From these results we deduce that the variation in density is slight but real. Therefore, in view of our vapor-density results and of this fact, we can state definitely that these constant-boiling distillates are mixtures and not compounds.

Making use of our density data we find that the constant-boiling mixture of water with pyridine contains 42% of water; with 2-methylpyridine, 48% of water; and with 3-methylpyridine, 61% of water. In the case of 2-methylpyridine this corresponds with the formula  $4\text{C}_6\text{H}_7\text{N} \cdot 19\text{H}_2\text{O}$ , and in the case of 3-methylpyridine, with  $3\text{C}_6\text{H}_7\text{N} \cdot 25\text{H}_2\text{O}$ , which is further confirmation of the non-existence of compounds.

TABLE III.

MISCIBILITY OF 2,4-DIMETHYLPYRIDINE<sup>6</sup> WITH WATER.

Water, % by Wt.	15.99	23.14	30.92	37.50	45.14	55.11	67.96	79.54	93.00	95.06
Lower solution point, °C.....	>150	>150	68.5	53.0	39.0	27.2	23.0	23.0	35.0	54.3

The minimum critical solution temperature is 22.5°. The composition of the constant-boiling mixture of 2,4-dimethylpyridine and water

<sup>5</sup> Roscoe, *J. Chem. Soc.*, 13, 146 (1861); 15, 270 (1862).

<sup>6</sup> The solubility of this base in water was determined by Alexéeff's method.

was determined by means of the solubility curve. A mixture of 2,4-dimethylpyridine and water was distilled, and the distillate which boiled constantly at  $96.5^{\circ}$  consisted of two layers. When the distillate was cooled below  $23.2^{\circ}$ , it became homogeneous. Reference to the miscibility data showed that it contained 66% of water.

### Summary.

The densities of aqueous solutions of pyridine, 2-methylpyridine and 3-methylpyridine have been determined. The compositions of the constant-boiling mixtures have also been ascertained, and found to be 42%, 48% and 61% of water respectively. Solubility data for 2,4-dimethylpyridine have also been given.

MANCHESTER, ENGLAND.

## A THEORY OF ALLOTROPY.

BY MAURICE COPISAROW.

Received November 18, 1920.

The term *allotropy* was first introduced by Berzelius,<sup>1</sup> as denoting the appearance of an element in several states distinguished from one another by different properties, a definition lacking in precision, owing to the numerous possible interpretations of the "different properties."

Allotropy is taken as a term covering the different physical states of matter, and also isomerism, polymerism and polymorphism,<sup>2</sup> and in this sense might appear, perhaps, to be an unnecessary term without exact meaning in chemical nomenclature.

This inclusion of different phenomena, along with Ostwald's and Nernst's definition of allotropy on the basis of energy changes, and Benedick's, Honda's and Le Chatelier's conception based upon the discontinuity of forms, phases and properties, is due to the consideration of *effects* of, instead of *causes* underlying phenomena.

While a close study of the various properties of matter consequent to a certain phenomenon may help us in comprehending the phenomenon itself and its relationship to other natural manifestations, it is wrong to define a phenomenon by its effects, especially when these effects are anything but specific or characteristic. A far truer and more productive definition would be based upon the study of the *causes* of a phenomenon, the unmasking of which should naturally throw much light upon the phenomenon itself and its probable effects.

The possible causes of allotropy may be either (a) a variation in the intramolecular structure of elements, or (b) a change in the intermolecular association or aggregation of elements.

<sup>1</sup> Berzelius, *Jahresber.* 20, [II] 13 (1841).

<sup>2</sup> Lehmann, *Z. Kryst. Min.*, 1, 97 (1877); Lowry, *Trans. Faraday.*, 11, 150 (1916).

Considering that (1) molecular aggregation subject to the laws of crystallography accounts for polymorphism,<sup>3</sup> and that (2) allotropic modifications present in most cases considerable chemical and physical differences, it would appear that allotropy is due to intramolecular differences.<sup>4</sup> We can regard allotropy not only as a function of valence, but also define it as the capacity of an element to exist in forms differing in the mode of their intramolecular linkage.

The conception of valence adopted by the author is that represented by the "primary valence" of Abegg and Werner.

This conception of allotropy is in full accord with (a) the hypothesis of dynamic allotropy,<sup>5</sup> as on this basis only a simple space lattice, revealed by the reflection of X-rays from the internal planes of crystals, can be deduced; and (b) the *view* of different ions existing in solution in presence of two allotropes of an element.<sup>6</sup>

In this sense allotropy, although a function of valence, does not imply isomerism or polymerism, as allotropes need not necessarily contain the same or a multiple number of atoms in their respective molecules. This conception of allotropy can be clearly understood on the basis of the electronic theory. According to this theory the valence bonds are considered as having a definite direction. The relative direction of these bonds in the molecule may be influenced by the conditions under which such a molecule is formed. Variation in the direction would give rise to molecular structures differing in the distribution of electric charges among the constituent atoms. These would be allotropes, and that configuration in which the charges were most symmetrically arranged or neutralized would be the stable form under these conditions.

Recognizing allotropy as a function of valence and knowing the valence of an element (the maximum one in case of elements of variable valence), we should be able to indicate not only the possible constitutional formulas of allotropes, but also the maximum number of allotropes possible for each individual element. Studying the possible constitutional formulas for molecules of elements on the basis of their valences we find that the problem resolves itself into the definition of the number of possible conditions or modes of freedom of an atom of the element in question.

I. An atom of the monoatomic *inert* gases can exist in *one* condition only.

<sup>3</sup> Wyroubow, *Bull. sos. min.*, **26**, 335 (1906).

<sup>4</sup> Blanshard, *Chem. News*, **70**, 295 (1894).

Köppel, *Naturw. Rund.*, **19**, 249, 261 (1904).

Guthrie, *J. Roy. Soc. N. S. Wales*, **14**, 318 (1911).

Oxley, *Trans. Faraday Soc.*, **11**, 129 (1916).

<sup>5</sup> Smits, *Verslag. Akad. Wetenschappen Amsterdam*, 19101-920.

<sup>6</sup> Holt, *J. Soc. Chem. Ind.*, **34**, 693 (1915).

II. An atom of a *monovalent* element can exist in *two* conditions only: (a) fixed valence,  $\cdot\text{---}$ ; (b) free valence,  $\cdot\text{---}$ . Halogens at high temperature and probably nascent hydrogen are cases of monovalent elements containing a free valence.

III. An atom of a *divalent* element may exist in *two* conditions only: (a) fixed valence,  $\cdot\text{---}$ ; (b) free valence,  $\text{---}\cdot\text{---}\cdot\text{---}$  or valences,  $\text{---}\cdot\text{---}$

IV. An atom of a *trivalent* element may exist in *two* forms only: (a) a saturated state with no free valences,  $\cdot\text{---}\cdot\text{---}\cdot\text{---}$ ; (b) an unsaturated condition with free valences,  $\cdot\text{---}$ ,  $\cdot\text{---}\cdot\text{---}$ ,  $\cdot\text{---}\cdot\text{---}\cdot\text{---}$ .

V. An atom of a tetra-, penta- or other polyvalent element may exist in *three* forms or conditions only: (a) a saturated condition, in which the atom is rigidly fixed,  $\cdot\text{---}\cdot\text{---}\cdot\text{---}\cdot\text{---}$ ,  $\cdot\text{---}\cdot\text{---}\cdot\text{---}\cdot\text{---}$ ; (b) an unsaturated condition, in which the atom is rigidly fixed by having three or more of its valences fixed,

(c) an unsaturated condition, in which the atom is not rigidly fixed,  $\text{---}\cdot\text{---}$ ,  $\cdot\text{---}\cdot\text{---}\cdot\text{---}$ ,  $\cdot\text{---}\cdot\text{---}\cdot\text{---}\cdot\text{---}$ .

It appears that while a polyvalent atom linked to one or two other atoms has the power of free rotation (the valences being regarded as axes, representing polar forces, the axis of rotation may not be common to any valence, but represented by the resolved effect of all valences concerned), an atom linked to 3 or more atoms has no such power of rotation, and can be regarded as rigidly fixed. As atoms of each condition can form by their combination with one another one and only one distinct molecular form, and as a combination of atoms, individually in different states, is most improbable, we are justified in concluding the maximum number of allotropic modifications of an element under the most favorable conditions of temperature and pressure (forms not necessarily occurring in *all* physical states) to be as follows: (1) the inert gases may exist in *one* form only; (2) the mono-, di-, and trivalent elements may exist in *two* forms only; and (3) the tetra-, penta- and other polyvalent elements may exist in not more than *three* distinct intramolecular forms.

While the valence of an element determines the number of possible allotropes, comparative examination of the chemical and physical properties of any element in all its forms should enable us to define with fair precision the intramolecular structure of each allotrope.

A scrutiny of the possible molecular forms of elements shows that theoretically it is possible for an element to have in certain cases more than one molecular form corresponding to each mode of linkage indicated above; that is, there may occur more than one form of an element with a rigid or non-rigid configuration. But regarding allotropes as the most chemically and physically distinct forms of an element it is obvious that several molecular forms, each containing a different number of atoms, but all having the power of free rotation, will differ among themselves to a less extent than when compared with a molecular structure of the same element, in which all atoms are rigidly fixed. Thus it follows that valence and the saturation or fixation of the atoms, and not the actual number of atoms, play the predominant part in the determination of allotropes. In this light allotropy becomes the capacity of an element to exist in forms differing in the mode of their intramolecular linkage. Molecular forms differing in the number of atoms or distribution of linkages, but all belonging to one and the same type of mode of linkage indicated above can be termed *allotropoids*. These molecular forms serve as a transition or link between polymorphism and allotropy proper. Each modification of an element, which is an allotropoid in relation to forms belonging to the same mode of linkage, is an allotrope when viewed in connection with modifications belonging to a different type of linkage. Allotropoids differ among themselves less in physical, and still less in chemical properties than allotropes of the same element.

The problem of discriminating between allotropy and polymorphism or intra- and inter-molecular structures,—comparatively easily solvable in the case of a few advanced characteristic instances, becomes therefore complicated and the available methods uncertain, not only owing to the inert character of some elements, which compels us to draw conclusions from their physical properties only, but also owing to the fact that in some cases we may deal with substances which are simultaneously either (1) allotropes and polymorphic forms, or (2) allotropoids and polymorphic forms. Thus the physical data may indicate the combined effect of intra- and inter-molecular rearrangements in the element; and as the components, the combination of which gives us the total effect, need not necessarily be magnitudes in the same direction, the physical data lose much of their comparative value.

The knowledge of the maximum possible number of allotropes, serving as a guiding limitation, augmented by the chemical and physical properties of the modifications, should be sufficient in most cases in identifying the

allotropes of an element. In cases where owing to the inertness of an element we have to depend upon the physical factor only, as many physical properties as possible are to be taken into consideration, since no single feature or property is sufficiently characteristic to serve as a decisive indication of allotropy. The functional connection of physical constants with the periodic system of atomic weights and volumes of elements make it very necessary, if any generalizations are to be made, to have the experimental conditions for the determination of physical constants specific for every element with special relation to the absolute melting and transition points of every modification of an element.<sup>7</sup>

Differences in crystalline symmetry are indefinite as a criterion or definition of allotropy, owing to the possibility of substances belonging either to different crystalline systems or different classes of the same system. The observation that the higher the crystalline symmetry of an element the smaller is the number of atoms constituting its molecule,<sup>8</sup> and consequently the smaller is its tendency to allotropy<sup>9</sup> is of an empirical character, and can hardly serve as a guiding principle in distinguishing allotropic from polymorphic forms, this being especially so as crystalline structures may depend at least as much upon molecular aggregation as on the intramolecular configuration of the atoms.

The sudden changes in the discontinuity of properties can be accepted as an indication of allotropy but with reserve, not only owing to the difficulty of establishing such discontinuity,<sup>10</sup> but also owing to the fact that such changes accompany both allotropy and polymorphism, and if there is any difference, it is in the degree, not the kind of change. The thermal changes so characteristic of the most pronounced allotropic transformations of the non-metallic elements, though often very useful as an indication, are not completely to be relied upon, as all thermal measurements for metals give decidedly lower values than for non-metals, and considerable changes of volume, hardness, porosity, electromotive forces, electrical resistance, specific heat, and the thermo-electric power are not necessarily accompanied by great heat changes. Considerable heat changes may be taken as a positive indication of allotropic rearrangement, but small heat changes are hardly safe as a negative proof, the more so as the heat evolution actually recorded may be the sum of two or more values of reactions, some exothermic and others endothermic.

As mentioned above, the allotropes of metals are more difficult to isolate and distinguish, than those of the non-metals. But even in cases

<sup>7</sup> Copisarow, *J. Inst. Metals*, **20**, 98 (1918).

<sup>8</sup> Retgers, *Z. physik. Chem.*, **14**, 1 (1894).

<sup>9</sup> Barlow and Pope, *J. Chem. Soc.*, **81**, 1741 (1906).

<sup>10</sup> Honda, *J. Iron Steel Inst.*, **91**, 199 (1915); *Science Repts. Tohoku Imp. Univ.*, [4] **3**, 261 (1915).

when no separate allotropic modifications have been isolated, (a) the dependence of such physical properties as density, specific heat, expansion, electrical conductivity, and the melting, solidification, and transition-points upon the thermal history of the specimen, and (b) the variation of the chemical behavior with the past history of the metal, are best explained on the basis of the allotropy hypothesis.

The constitutional formulas of allotropes developed on the basis of valence and the chemical and physical properties of each modification, although not actually solving the interesting problem of molecular complexity, offer us substantial aid in this respect, insofar as they often indicate the minimum molecular complexity satisfying the requirements of the formulas.

The consideration of the allotropy of elements, applying to elements mainly in their solid state, throws incidentally much light upon the general constitution of the solid state of matter.

The modern X-ray spectrometric investigations, though failing to indicate the display of forces between atoms, are showing the positions of atoms in space, thus affording a possible method of study of allotropes. Now as characteristic cases of allotropy we may discuss the allotropy of phosphorus, carbon, iron and nickel.

### Allotropy of Phosphorus.

The number of forms of phosphorus recorded from time to time in the literature is considerable. In several instances, however, a difference in color, mode of fracture, size of particles or slight deviation in the specific gravity (regardless of impurities) was taken as a sufficient basis for the announcement of a new form of phosphorus.

In addition to the white (ordinary, colorless or yellow) and red phosphorus, the following are described as distinct modifications: (1) *black* phosphorus (Thénard<sup>11</sup>); (2) *red* phosphorus, soluble in alkalis (Schenck<sup>12</sup>); (3) *scarlet* (ruby-red) phosphorus (Troost and Hautefeuille<sup>13</sup>); (4) *dense-red* phosphorus (Bridgman<sup>14</sup>); (5) *violet* (metallic or crystalline) phosphorus (Hittorf<sup>15</sup>); (6) *black* phosphorus (Bridgman<sup>14</sup>). Thénard's black phosphorus was proved by Blondlot, Ritter and Gernez<sup>16</sup> to be ordinary red phosphorus, contaminated with mercury and arsenic. Schenck's soluble red phosphorus appears to be ordinary red phosphorus in a state

<sup>11</sup> Thénard, *Compt. rend.*, **95**, 409 (1882).

<sup>12</sup> Schenck, *Ber.*, **36**, 979, 4202 (1903).

<sup>13</sup> Troost and Hautefeuille, *Compt. rend.*, **78**, 748 (1874).

<sup>14</sup> Bridgman, *THIS JOURNAL*, **36**, 1344 (1914).

<sup>15</sup> Hittorf, *Pogg. Ann.*, **126**, 193 (1865).

<sup>16</sup> Blondlot, *Compt. rend.*, **70**, 856 (1870); **78**, 1130 (1874). Ritter, *ibid.*, **78**, 192 (1874). Gernez, *ibid.*, **151**, 12 (1910).

of fine division.<sup>17</sup> Troost and Hautefeuille's intensely colored form of phosphorus, as well as Bridgman's dense-red phosphorus, differing from red and Hittorf's violet modifications in no other property than color and a very slight deviation in specific gravity, must be regarded as belonging to one of the latter forms. Notwithstanding the considerable attention paid by investigators to ordinary red and Hittorf's violet phosphorus the question of their distinct character or individuality still remains unsettled.<sup>18</sup> But even assuming that red and violet phosphorus exist as two separate forms, we must admit that the very slight difference in physical properties, and the absence of any chemical differences make the contrast between red and violet phosphorus in no way as pronounced as that with either white or Bridgman's black modification. The character of the possible co-existence of red and violet phosphorus will be discussed at a later stage. Black phosphorus<sup>19</sup> must be regarded as a distinct modification of phosphorus, as it is characterized by its high density, conductivity of heat and electricity, low specific heat and vapor pressure, and general stability. Thus we find that phosphorus occurs in three chemically and physically distinct forms: (1) white, colorless or yellow; (2) red, and Hittorf's violet or metallic; and (3) black phosphorus.

Now on the basis of the theory of allotropy phosphorus, being pentavalent, may exist in *not more* than three chemically and physically distinct forms: (I) a *non-rigid* molecular form, in which *some* valences are

form, *some* valences of which are *free* (Fig. 1, tetrahedron); (III) a *rigid* molecular form, *all* valences of which are *fixed* (Fig. 2, icosahedron).

It is clear from the three constitutional formulas that a molecule represented by non-rigid configuration (Class I) will be characterized by comparative reactivity, small specific gravity, high vapor pressure, low melting point, etc.

A molecule represented by a rigid configuration (Class III) will exhibit properties exactly opposite to those just indicated, while the molecular structure, Class II, will be intermediate in all its properties. Comparing

ular configurations, we find no difficulty in assigning to each distinct form of phosphorus its constitution formula, *viz.*, white, Class I; red, Class II; and black, Class III.

The following considerations show not only the existence of a striking agreement between the theory of allotropy and the deductions based upon it, and the experimental facts, but also the remarkable way in which this theory elucidates and consolidates isolated and uninterpreted facts.

1. Class I may be taken as a just representation of the constitution of both white phosphorus and phosphorus vapor since the molecular complexity of white phosphorus,<sup>20</sup> as well as that of phosphorus vapor<sup>21</sup> is represented by  $P_4$  and the transition of white phosphorus to vapor is reversible.<sup>21</sup>

2. A regular tetrahedron ( $P_4$ ), is a correct representation of the molecular constitution of red phosphorus, as (a) the vapors of white, red and black phosphorus are identical; (b) the transition from red phosphorus

<sup>20</sup> Schenck, *Ber.*, **35**, 351 (1902).

Beckmann, *ibid.*, **5**, 76 (1890).

Chapman, *J. Chem. Soc.*, **75**, 735 (1899).

to vapor is irreversible; and (c) the transformation of white to red phosphorus is a monomolecular reaction.<sup>22</sup>

The transformation of white to red phosphorus is represented by the passage from a *plane* configuration to a *three-dimensional* structure.

3. A close examination of the constitution formulas deduced above for white, red and black phosphorus offers us a clear explanation of the fact observed by Bridgman,<sup>19</sup> *i. e.*, the transformation of white phosphorus to black, and the failure of red (or violet) to undergo such a change.

No polymerization unaccompanied by a complete disruption of the molecule can transform a molecular structure represented by a tetrahedron (red phosphorus) into one represented by a regular icosahedron (black phosphorus). On the other hand the transformation of white phosphorus to black is constitutionally a simple polymerization closely resembling the acetylene  $\rightarrow$  benzene transformation, *viz.*,  $3 P_4 = P_{12}$ .

Following up this polymerization we see that there is a probability of an intermediate stage or form between white and black phosphorus.

The *plane* configuration of white phosphorus probably passes at 200° and 11000–12000 kg./cm<sup>2</sup>. pressure, through an asymmetric, apparently unstable, *two-plane* form, before polymerizing to black phosphorus.

This consideration is in remarkable agreement with Bridgman's observation of a preliminary reaction, a "preparation-period" in the transformation of white to black phosphorus.

The question of violet phosphorus, as previously indicated, is still unsettled; but even assuming that violet phosphorus is a distinct form, such an assumption would in no way undermine the validity of the theory of allotropy.

As indicated in the theory of allotropy in case of polyvalent elements more than one molecular form, belonging to the same type of configuration, is possible, *i. e.*, molecular forms differing in the number of atoms, without any radical difference in the mode of linkage. Thus a molecular con-

<sup>22</sup> Schenck, *Ber.*, 36, 4202 (1903).

figuration,  $P_8$ , represented by a cube (see Fig. 3) would offer a satisfactory conception of the constitution of violet phosphorus, as such representation similar to Fig. 1 assigned to red phosphorus would be a *rigid* form, containing *free* valences. A molecular form of such constitution, a direct product of polymerization of white phosphorus by the condensation of two molecules, would be quite tangible, as the conditions of transformation of white to violet are more drastic than those of white to red phosphorus.

Fig. 3.

Therefore, should the separate existence of red and violet phosphorus be established, they will have to be regarded as *allotropoids* in relation to each other, and as *allotropes* in relation to *white* and *black* phosphorus.  $P_1$  and  $P_2$ , the high temperature dissociation products of phosphorus vapor,<sup>23</sup> belonging qualitatively to the molecular structure represented by by Class I are hence *allotropoids* in relation to the vapor  $P_4$  and white phosphorus, and *allotropes* in relation to red (violet) and black phosphorus.

### Allotropy of Carbon.

In the light of the chemistry of carbon compounds a carbon atom can be regarded as always potentially tetravalent. The polyatomicity of a carbon molecule is proved by (1) the existence of several distinct forms of carbon; (2) the high volatilization point of carbon; (3) the products of moist oxidation; (4) the combustion of carbon;<sup>24</sup> (5) the X-ray spectroscopic study of the modifications of carbon.<sup>25</sup> Attempts have been made to study the complexity of carbon molecules and to establish the constitutional molecular formulas of one or more forms of carbon by Kekulé,<sup>26</sup> Vaubel,<sup>27</sup> Barlow and Pope,<sup>28</sup> Dewar,<sup>29</sup> Aschan,<sup>30</sup> Dimroth and Kerkovius,<sup>31</sup> Bragg,<sup>32</sup> Meyer,<sup>33</sup> and Debye and Scherrer.<sup>25</sup>

Reviewing these investigations we find that a method of study so general as to be applicable to all forms of carbon has not yet been proposed.

<sup>23</sup> Preuner and Brockmöller, *Z. physik. Chem.*, **18**, 129 (1913).

Stock and Stamm, *Ber.*, **46**, 3497 (1913).

<sup>24</sup> Rhead and Wheeler, *J. Chem. Soc.*, **97**, 2181 (1910); **99**, 1140 (1911); **103**, 461 (1913).

<sup>25</sup> Debye and Scherrer, *Physik. Z.*, **17**, 277 (1916); **18**, 291 (1917).

Olie and Byl, *Verslag Akad. Wetenschappen Amsterdam*, **19**, 920 (1917).

<sup>26</sup> Kekulé, *Z. angew. Chem.*, **12**, 950 (1899).

<sup>27</sup> Vaubel, *ibid.*, **13**, 60 (1900).

<sup>28</sup> Barlow and Pope, *J. Chem. Soc.*, **89**, 1742 (1906).

<sup>29</sup> Dewar, *Chem. News*, **97**, 16 (1908).

<sup>30</sup> Aschan, *Chem. Ztg.*, **33**, 561 (1909).

<sup>31</sup> Dimroth and Kerkovius, *Ann.*, **399**, 120 (1913).

<sup>32</sup> Bragg, *Proc. Roy. Soc.*, **89A**, 280 (1913).

<sup>33</sup> Meyer, *Monatsh.*, **35**, 163 (1914).

While the method of moist oxidation can be applied more or less successfully to amorphous carbon and to some extent to graphite, the X-ray method is confined to diamond with a somewhat strained extension to graphite.

Now if we consider the problem from the point of view of valence, *i. e.*, molecular structure, we secure at once a general method of investigation. In the light of the theory of allotropy, carbon having a valence greater than three may exist in three distinct molecular forms: (I) a *non-rigid*

molecular configuration, some valences of which are *free* (see also Fig. 4); (II) a *rigid* molecular configuration, some valences of which are *free* (see Fig. 5); and (III) a *rigid* molecular configuration, all valences of which are fixed (see Fig. 6).

Fig. 4.

Fig. 5.

The several new modifications of carbon (graphitoid, graphitite, etc.) suggested by Brodie, Berthelot, Luzi and others have been proved to be either compounds, solutions or mixtures of carbon with some other elements.<sup>34</sup>

Debye and Scherrer's<sup>25</sup> experiments merely indicate the presence of graphite in amorphous carbon, and the absence of other crystalline forms. These experiments afford, however, no ground for the unification of graphite with amorphous carbon.

No matter how finely divided graphite may be (Acheson's or "colloidal" graphite), its behavior towards moist oxidants, its products of oxidation, mode of combustion and physical properties—all greatly differ from those of amorphous carbon.

Meyer<sup>33</sup> and Meyer and Steiner,<sup>35</sup> recording the dependence of the yield of mellitic acid from charcoal upon the latter's source and temperature of carbonization, express some doubt as to the entity of the carbon "molecule" and the close connection of its constitution with the product of oxidation. Now the yield of mellitic acid *does* vary with the sources of the charcoal employed, and the temperature, pressure and duration of carbonization; but the formation of the mellitic acid cannot be attributed to the presence of complex hydrocarbons, possibly retained by the charcoal carbonized at a comparatively low temperature, since a quantitative determination of the percentage of hydrogen, oxygen and nitrogen, invariably accompanying this kind of charcoal, gives not more than 1% of these elements, while the yield of mellitic acid reaches as high a value as 40%. The dark residue "mellogen,"<sup>36</sup> remaining after the first oxidation, gives on exhaustive oxidation again mellitic acid and also some oxalic acid. To attribute the varying yields of mellitic acid to the existence of several modifications of amorphous carbon, as some investigators are inclined to do, is quite unwarranted, as such an explanation of the somewhat varying quality and properties of charcoal would necessitate the assumption of a whole series of modifications of amorphous carbon, corresponding to every source of charcoal and practically to every change of 20° to 50° in the temperature of carbonization. The causes of the dissimilar behavior of various samples of charcoal are probably much simpler. Such causes may be (a) a high temperature of carbonization, which reducing the porosity of the resulting amorphous carbon or charcoal, increases in consequence its resistance to oxidation; (b) a high temperature of carbonization, which facilitates the conversion of amorphous carbon into graphite, so that we may deal with charcoal containing a high percentage of finely divided graphite;<sup>37</sup> (c) a high percentage of mineral matter,

contaminating charcoal, may affect its properties in more than one way.

Thus we find that there are three distinct forms of carbon, corresponding to the three, theoretically possible, fundamentally different configurations. The following considerations may help to assign to each modification its constitutional formula. The calorimetric measurements of the heat of complete combustion of carbon per gram-atom give<sup>38</sup> for amorphous carbon, 97.650 Cals.; for graphite, 94.810 Cals.; and for diamond, 94.310 Cals. These figures indicate the sum total of the energy liberated during the formation and degradation of the possible complexes<sup>24</sup> plus that of the oxidation of the carbon monoxide to carbon dioxide.

It must be noted that the calorimetric measurements of the heats of combustion of the modifications of carbon differ considerably with every experimenter.<sup>39</sup> Taking equal weights of amorphous carbon, graphite and diamond, and subjecting them to complete combustion, we find that the amount of heat evolved is different for each form of carbon, although the number of atoms taken and the number of molecules of carbon dioxide formed is identical in all cases.

Looking for the cause of this dissimilarity of thermic values we are driven to attribute it to the different stabilities of the molecules in the three cases, which must depend upon the mode of linkage of the units constituting the molecule, as well as the complexity of the molecule itself.

Returning to our classification of theoretically possible configurations we expect that the least stability will be exhibited by molecules whose units have the power of free rotation or, in other words, which have more than one free valence; the maximum stability will be found in the molecule, all constituent units of which are in a state of rigidity and all valences fixed; the intermediate case being a molecule which has some valences free, but a rigid structure.

Now considering the fact that the greater the stability the smaller will be the evolution of heat on complete combustion (compare the case of phosphorus), and correlating this with the calorimetric measurements quoted above, we find that amorphous carbon is represented by Class I, where *none of the atoms* is rigid; graphite by Class II, where the atoms are rigid, but *some* valences free; and diamond by Class III, in which all atoms are rigid and *all* valences fixed. These deductions find strong support in the character of the products of the moist oxidation of carbon. The molecule of amorphous carbon with none of its units rigidly fixed, as might be expected, is the least resisting to oxidants and yields mellitic

acid. Graphite with its partly fixed units gives rise to graphitic oxide or acid, an acid more complex than mellitic. The rigidly fixed units of diamond are practically unaffected under the same conditions of oxidation.<sup>35,40</sup>

Similar to the heats of combustion we may expect the values of any other physical property to show a regular gradation from amorphous carbon to the diamond, the value for graphite lying between the values for the two other forms, such gradation serving as confirming evidence in support of the theory under discussion. Below are collected the values for a number of physical constants, which have been determined for all three forms of carbon. The numbers are taken from Landolt-Börnstein, "Tabellen," 4th Edition, 1912.

TABLE I.  
Properties of Carbon.

	Density.	Coefficient of cubical expansion.	Thermal conductivity.	Specific heat. <sup>42</sup>	Electrical conductivity.
Diamond	3.51	0.00000375	0.33(0°) <sup>41</sup>	0.1128(10.7°)	$\left\{ \begin{array}{l} 0.211 \times 10^{-14} \text{ to} \\ 0.309 \times 10^{-13} (15^\circ) \end{array} \right.$
Graphite	2.10-2.32	0.0000104	0.0117	0.1604 <sup>a</sup> (10.8°)	0.0802 $\times 10^4$ (15°)
Amorphous carbon					
Gas coke	1.885	0.0000162			
Coconut charcoal	1.67-1.86				
Lamp black, sugar charcoal and wood charcoal	1.70-1.80		0.000405	0.1653(0-24°)	0.25(12°)

<sup>a</sup> Ceylon graphite.

An inspection of this table shows that, with the single exception of the electrical conductivity, all the physical properties are in the order we should expect. In the case of the electrical conductivity graphite occupies an anomalous position, in that its conductivity is very much greater than that of either the diamond or amorphous carbon. The explanation may be found in the fact that in diamond *all* electrons, being immobilized in linkages, leave *none* free to conduct a current, while in graphite the single free valence, serving as a directive, polar force, facilitates the electric current. Amorphous carbon with its several free valences—counter-acting forces—occupies an intermediate position.

The elucidation of the molecular structure of the carbon allotropes throws much light upon the mechanism of the combustion of carbon, a problem which has received a good deal of attention.

Under the stress of experimental evidence the *reduction theory* of Lang<sup>43</sup> has been replaced by that of *gradual oxidation* by Baker<sup>44</sup> and Dixon,<sup>45</sup> which in its turn is being replaced by the *theory of complexes*, proposed by Rhead and Wheeler.<sup>24</sup>

The conception of a non-rigid configuration containing free valences, for amorphous carbon, affords a complete explanation of (1) the comparatively easy combustibility of this form of carbon; and (2) the simultaneous evolution of carbon monoxide and dioxide, products of disruption of the complexes, logically constituting the first stage of oxidation. The conception of a rigid configuration for diamond and graphite explains the considerable resistance to combustion exhibited by these allotropes, and suggests that no intermediate complexes, assumed in the case of amorphous carbon, are likely in the course of combustion of diamond.

### Allotropy of Iron and Nickel.

The lack of distinctive chemical properties makes the recognition of separate forms of iron practically dependent upon the variation of physical properties, as indicated by transition points. The study of the graphs, representing the changes of temperature, volume,<sup>46</sup> tenacity, electrical conductivity<sup>47</sup> and the solubility of carbon and hydrogen<sup>48</sup> indicates there transition points, *viz.*, at 769°, 906° and 1401°, the solidification point<sup>49</sup> of iron lying at 1528°.

The precision of the determinations of the transition points is greatly influenced by the impurities (carbon, hydrogen, nickel, etc.) persistently

accompanying iron. The presence of these impurities results in the depression of the transition points, which converge gradually to one point at  $700^{\circ}$ .<sup>50</sup> The persistence of impurities in iron can be seen from the fact that electric measurements of even the purest iron show as much as 0.27% of carbon<sup>48</sup> (0.08% according to Fournel<sup>47</sup>).

The experimental data on the comparative hardness of the modifications of iron are conflicting, owing to the disturbing factors of the different solubilities and varying percentages of dissolved carbon,<sup>51</sup> etc. While the  $\beta \rightleftharpoons \gamma$  and the  $\gamma \rightleftharpoons \delta$  transitions, as indicated by the specific heat, thermal measurements,<sup>52</sup> electrical resistance, change of crystal structure,<sup>53</sup> dilation,<sup>54</sup> electromotive forces<sup>55</sup> and magnetism,<sup>56</sup> are definite and sudden, the  $\alpha \rightleftharpoons \beta$  transition is gradual, extending over a range of  $40^{\circ}$  to  $100^{\circ}$ , and is accompanied by a change of magnetic properties.<sup>57</sup> The study of the specific heat indicates that the  $\alpha \rightleftharpoons \beta$  transformation is completed by a continuous series of mixed crystals.<sup>58</sup> These fundamental differences revealed in the course of a comparative study of the transition points of iron make it manifest that the  $\alpha \rightleftharpoons \beta$  critical point, or rather range, cannot be regarded as a true allotropic change.<sup>52,59</sup> The  $\alpha \rightleftharpoons \beta$  transformation point may be regarded as merely the termination of the  $\alpha \rightleftharpoons \gamma$  change. The  $\beta$  form is simply a solid solution of  $\gamma$  in  $\alpha$ , the proportion of  $\gamma$  iron increasing with temperature.<sup>60</sup> Thus  $\alpha \rightleftharpoons \beta$  is the point at which  $\gamma$  ceases to be metastable and becomes unstable. This point is enhanced by impurities becoming in quenched steel as definite as the  $\beta \rightleftharpoons \gamma$  point,<sup>58</sup> and vanishes gradually with the decrease of the percentage of solid and gaseous matter dissolved in the iron.<sup>61</sup>

<sup>61</sup> Carpenter, *ibid.*, **87**, 326 (1913).

The loss of magnetism at the  $\alpha \rightleftharpoons \beta$  point is therefore due not merely to the increased velocity of vibration of the molecules, but to the formation of  $\gamma$  in  $\alpha$  iron, the former not only reducing the "effective section" of the conducting substance, but also breaking the current lines, when beyond a certain limit, thus resulting in a rapid fall of intensity in the magnetic forces.<sup>62</sup> Another view is that the  $\alpha \rightleftharpoons \beta$  transformation, accompanied by loss of magnetism, is a polymorphic change, magnetism being due either to a polar arrangement of molecules,<sup>63</sup> or to a specific property of the  $\alpha$  form of iron.<sup>64</sup>

Fig. 7.

Thus we find that the  $\alpha$ ,  $\gamma$  and  $\delta$  iron are the forms recognized as having a separate existence.<sup>65</sup>

Now in the light of the theory of allotropy, a trivalent element (as iron always is potentially) may exist in two distinct molecular forms: (I) a saturated molecular configuration, having no free valences (see Fig. 7), and (II) an unsaturated molecular form, having free valences;

Considering that practically all experimental evidence tends to show that the  $\alpha \rightleftharpoons \beta$  point is merely a retardation of the  $\alpha \rightleftharpoons \gamma$  transition point, thus disposing of the  $\beta$  form, and also the fact that the  $\gamma \rightleftharpoons \delta$  point, although sharply defined, is of a considerably smaller magnitude than the  $\alpha \rightleftharpoons \gamma$  change, we may take the two theoretically possible forms to correspond to the  $\alpha$  and  $\gamma$  forms of iron.

Considering that (a) generally molecular complexity decreases with the rise of temperature, and that (b) according to the magneton theory<sup>66</sup> molecular complexity decreases from  $\alpha$  to  $\gamma$ , we may take it that the  $\alpha$  form is represented by the saturated molecular configuration (tetrahedron), and  $\gamma$  by an unsaturated molecular form. The  $\delta$  modification formed at high temperature and differing from  $\gamma$  to a less degree than  $\alpha$ , can be re-

<sup>66</sup> Weiss, *Compt. rend.*, **152**, 688 (1911).

garded<sup>67</sup> as an *allotropoid*; *i. e.*,  $\gamma$  and  $\delta$  both belong to the same type or class of molecular configuration (unsaturated), but each differs from the other in complexity,  $\gamma$ -iron being represented by a tri-atomic and  $\delta$  iron by a di-atomic molecule.

The vapor of iron is probably mono-atomic, similar to mercury, phosphorus and the halogens at high temperature. The vapor of iron would thus together with  $\gamma$  and  $\delta$  iron form three allotropoids, belonging to the same type of molecular configuration. The molecular complexity of the modifications of iron may thus be represented in the following tabular form.

Forms of iron.	Transition temperatures. ° C.	Minimum molecular complexity, or number of atoms in the molecule.
$\alpha$	906	4
$\gamma$	1401	3
$\delta$	1528	2
Vapor		1

The conception of the various forms of iron as being due not to molecular differences, but to different groupings of atoms<sup>68</sup> explains nothing, and represents a misinterpretation of the recent X-ray spectrometric work.

### Allotropy of Nickel.

The transformation of nickel has received considerably less attention than that of iron. Nevertheless sufficient data are available to show that the main transition point lies at 345–346°, being accompanied by a change in the rate of loss of permeability, coefficient of expansion, specific heat, magnetic and thermo-electric properties and electrical conductivity.

The fact that the several determinations of the transition point of nickel vary within 20° to 25°, is probably due not only to the different methods of determination, but also in a large degree to the different states of purity of the nickel under investigation.

A second transition point, decidedly less pronounced, accompanied by a change in crystalline form, has been observed<sup>69</sup> at 700°. These transition-points resemble the  $\beta \rightleftharpoons \gamma$  and  $\gamma \rightleftharpoons \delta$  changes in iron, and we can with sufficient justification draw the same conclusion as to the molecular complexity of the forms of nickel, as in the case of iron.

# AROMATIC MERCURI-ORGANIC DERIVATIVES. THE HOFMANN REARRANGEMENT AND THE NATURE OF VALENCES OF MERCURY IN MERCURI-ORGANIC DERIVATIVES.

BY MORRIS S. KHARASCH.<sup>1</sup>

Received January 29, 1921.

The effect of the halogens on mercury diphenyl has been studied by Otto<sup>2</sup> who found that bromine (one molecule) in water solution or in anhydrous media, gave rise to phenyl mercury bromide, and phenyl bromide. When, however, an excess of bromine was used, the resulting products were mercuric bromide and phenyl bromide. The behavior of mercury diphenyl with bromine is representative of the behavior with any other halogen. With the halogen acids the result was similar but, of course, instead of the phenyl halide, benzene was the other product. It was, therefore, of interest to find out just what the effect of positive halogen<sup>3</sup> alone on mercury diphenyl would be.

It was with this idea in mind that the effect of N-bromo-acetamide in sodium-dried benzene upon mercury diphenyl, dissolved in the same solvent, was tried. After the solution was warmed for about 10 minutes on the water-bath, a solid separated which was identified as phenyl mercury bromide.<sup>4</sup>

The reaction when studied in greater detail, and also, with other N-bromo-amides revealed the fact that mercury diphenyl played the same part in this reaction as sodium hydroxide in aqueous solution and sodium ethylate in absolute alcohol,<sup>5</sup> and that it also led to a rearrangement in which the group attached to the carbon migrated to the nitrogen.

<sup>1</sup> National Research Fellow in Organic Chemistry.

<sup>2</sup> Otto, *J. prakt. Chem.*, [2] 1, 182 (1870).

<sup>3</sup> Seliwanow, *Ber.*, 25, 3617 (1892); Lengfeld and Stieglitz, *Am. Chem. J.*, 15, 215, 504 (1893); W. A. Noyes, *THIS JOURNAL*, 23, 450 (1901); J. Stieglitz, *ibid.*, 23, 796 (1901), etc.

<sup>4</sup> The same reaction takes place also in bright sunlight in the course of a few minutes, without any heating whatsoever.

<sup>5</sup> Lengfeld and Stieglitz, *Am. Chem. J.*, 15, 215, 504 (1893).

Furthermore, we find that just as sodium hydroxide or sodium ethylate fails to effect a rearrangement in the case of the N-substituted alkyl or aryl bromo- and chloro-acetamides,<sup>6</sup> so mercury diphenyl seems not to be acted upon by the latter reagent. Even after prolonged boiling (12 to 14 hours), no action occurs, although N-chloro-acetanilide is a chlorinating agent in anhydrous media. Thus, when the latter was treated with aniline in dry benzene, 2,4-dichloro-aniline and acetanilide were formed. Also dimethyl aniline, diphenylamine, and *m*-dimethylamino-acetyl phenol gave acetanilide and chlorinated products, while triphenylamine and *m*-nitro-dimethylaniline were not acted upon at all.

Thus, the reaction of mercury diphenyl and the N-bromo amides affords an excellent illustration of the basicity of mercury diaryl compounds. Of course, we must distinguish bases derived from hydrides which acquire their basicity through two additional valences, one positive and one negative, forming

where X is negative, such as ammonium, sulfonium, oxonium, iodonium and similar bases, and those derived from metal hydroxides, M(OH)<sub>2</sub>, where M is positive, *e. g.*, the derivatives of zinc, magnesium, mercury, etc. Mercury compounds of the type R-Hg-R and R-Hg-OH could well be, and probably are, derived from mercuric hydroxide Hg(OH)<sub>2</sub> giving

— ++ —      — ++ —  
them the structure R-Hg-R and R-Hg-OH respectively. In the case of the latter compounds, which are strong bases, the substitution could easily bring out the high ionizing tendency of a univalent base, comparable with silver hydroxide. Mercury diaryl compounds in benzene solution are then quite comparable to calcium hydroxide in aqueous solution,<sup>7</sup> which may be considered as the metal hydroxide or salt of the very weak

++ —  
acid water. Mercury diphenyl Hg (R)<sub>2</sub> is therefore a base of the benzene  
+ —  
system, as sodium amide NaNH<sub>2</sub> is a base of the ammonium system, sodium hydroxide of the aqueous system, etc.

A different view point as to the electronic structure of mercury dialkyl and diaryl compounds is held by Jones and Werner.<sup>8</sup> These authors assume that in these substances one of the valences of mercury functions positively and the other negatively, *i. e.*, to give a compound of the type

<sup>6</sup> Stieglitz and Slosson, *Ber.*, 28, 3266; 34, 1613 (1901); Slosson, *Am. Chem. J.*, 29, 289 (1903).

<sup>7</sup> The same view point has been maintained by Stieglitz for some years for the zinc methyl derivatives. Stieglitz, "Qualitative Chemical Analyses," 1, 177 (1911). See also Jones, *THIS JOURNAL*, 40, 1250 (1918).

<sup>8</sup> Jones and Werner, *ibid.*, 40, 1257 (1918).

— + — +

R-Hg-R. The experimental evidence for this assumption is confined to the study of the behavior of mercury diethyl, di-*iso*-amyl and dibenzyl. At high temperatures, these decompose to give metallic mercury and a

+ —

hydrocarbon R-R. Upon hydrolysis with glacial acetic acid, again at high temperatures, these give, for instance, in the case of mercury dibenzyl, metallic mercury, benzyl acetate, toluene and dibenzyl.

Jones and Werner, therefore, infer that if a compound upon hydrolysis gives metallic mercury, an alcohol, and a hydrocarbon, its electronic struc-

— + — +

ture must be R-Hg-R. While the validity of such reasoning is unquestioned it can be shown very readily that Jones and Werner's experimental data do not necessitate such a conclusion—one that is quite in disagreement with the position of mercury in the periodic system—and that direct experimental evidence that the valences of mercury function in any way but positively in all mercuri-organic derivatives is still lacking.

In the first place, we know that mercury in all inorganic compounds functions positively, and we should expect, therefore, that a bond between negatively charged mercury and a positive radical would be less stable than one between a positive mercury and a negative radical. This is in direct contradiction to Jones and Werner's formula which requires that the more stable union be ruptured first, when compounds of the type

— + — +

R-Hg-R are treated with acids, the following taking place, according to Jones and Werner.

Furthermore, Jones and Werner seem to ignore entirely the fact that mercuric ion is an oxidizing agent, the oxidizing power of which increases with the temperature. Thus stannous ion is oxidized by mercuric ion to the stannic ion, even at ordinary temperatures. Again, a good many organic compounds more or less sensitive to oxidation are oxidized by mercuric ion; dimethyl-*p*-phenylene-diamine is first oxidized to Wurster's red by a solution of mercuric acetate, and at a somewhat higher temperature metallic mercury is thrown out. The same is true of hydroquinone. In view of these facts one must always be on the lookout for the oxidizing tendency of the mercuric ion especially when working with mercury compounds at high temperatures.

If we bear this fundamental property of mercury in mind, the reactions of aryl and alkyl mercury compounds studied by Jones and Werner do not then necessitate the assumptions made by those writers. Thus, they started with 15 g. of mercury dibenzyl and after heating it for 7 hours at 200° isolated the following products in the quantities given: mercury 7.776 g.; toluene, 1.756 g.; benzyl acetate, 2.267 g.; dibenzyl,

3.05 g. These results show convincingly that two reactions took place simultaneously. In the first place, part of the mercury dibenzyl, namely 7.9 g., was transformed into metallic mercury and dibenzyl,<sup>9</sup> and the rest (7.1 g.) into mercury, toluene and benzyl acetate. In the latter case, the reaction undoubtedly takes place in the following stages.

In the benzyl mercuric acetate thus formed, at the high temperature used, the doubly positive mercury atom oxidizes the carbon and we get benzyl acetate and mercury, *i. e.*,

There is, therefore, nothing unusual about all the reactions mentioned by Jones and Werner. The reaction is simply a case of intramolecular oxidation and reduction and quite comparable with the molecular rearrangements which take place due to intramolecular oxidation and reduction.<sup>10</sup> Again, the decomposition of mercury compounds by chlorine, bromine and iodine, taken in connection with the decomposition by acids,<sup>11</sup> lends more weight to the well accepted fact that mercury always functions positively in all mercuri-organic compounds.

We might add also that at no time do results obtained by the use of high temperatures prove anything as to the electronic structure of the starting product. As yet, we are quite ignorant of the changes which take place at high temperatures. Thus, the formation of diphenyl alone, at a high temperature, from benzene would be a very poor argument that, in benzene, we have two tautomeric electromers in equilibrium:  $\text{C}_6\text{H}_5\text{--H} \rightleftharpoons \text{C}_6\text{H}_5\text{--H}$ ; and Jones and Werner carried out the hydrolysis of mercury dialkyl and diaryl compounds at temperatures ranging from 170° to 220°.

<sup>9</sup> This observation was made by Wolff [*Ber.*, 46, 64 (1913)] who states that when mercury dibenzyl is heated above its melting point, 111°, it is decomposed into metallic mercury and dibenzyl.

<sup>10</sup> L. W. Jones, *Am. Chem. J.*, 48, 1 (1912); 50, 440 (1913). J. Stieglitz, *Ber.*, 43, 782 (1910); *This Journal*, 36, 287 (1914); *Ber.*, 46, 2149 (1913).

<sup>11</sup> Jones and Werner have to assume the existence of two tautomeric electromers  $\text{R--Hg--R} \rightleftharpoons \text{R--Hg--R}$ , to explain the decomposition of mercury dialkyl and diaryl compounds by conc. hydrochloric acid, *i. e.*, mercuricchloride and a hydrocarbon being the products.

Summing up, we might say that from experimental work described in this paper, and the behavior of mercury diaryl compounds, in general,

— ++ —

the structure  $R-Hg-R$  is the most appropriate one: it explains the reactions of mercury diaryl and dialkyl compounds without any additional postulates and is in perfect agreement with the chemistry of the element.

### Experimental.

**Action of Mercury Diphenyl on N-Bromo-amides. N-Bromo-acetamide.**—Of this 0.6 g. was dissolved in dried benzene,<sup>12</sup> and then treated with 1.3 g. of mercury diphenyl dissolved in 40 cc. of benzene. The solution was then boiled for 20 minutes at the end of which time no active bromine could be detected in it. A white crystalline compound separated, and the solution had a pungent, irritating odor very characteristic of an isocyanate. The precipitate was collected on a filter, care being taken not to allow any atmospheric moisture to come in contact with the filtrate. The precipitate thus obtained (0.7 g.) melted at 276°. After a single crystallization it melted at 291°. When the compound was mixed with some known phenyl mercuric bromide the melting point of the latter was not lowered.

The filtrate from the phenyl mercury bromide contained some phenyl mercury bromide, a little unchanged mercury diphenyl and methyl isocyanate. To separate the latter from other compounds, dry aniline was added<sup>13</sup> to the filtrate to form methyl-phenyl urea. The mixture was warmed for 3 minutes at 60°, cooled and ligroin added until the solution became turbid. Beautiful white needles were thus obtained, m. p. 152° to 153°. The melting point of  $\alpha,\beta$ -phenyl-methyl urea given in the literature is 150°.

The urea thus obtained exhibits the reactions given in the literature for phenyl-methyl urea ( $\alpha, \beta$ ), *i. e.*, when a minute quantity of it was dissolved in conc. sulfuric acid and a little powdered potassium dichromate added to it, an intense maroon color was imparted to the solution.

The same arrangement is also effected if the solution of N-bromo-acetamide and mercury diphenyl is allowed to stand in bright sunlight for 3 to 4 minutes. In the dark however, the reaction takes place very slowly as indicated by the fact that after a lapse of two weeks there was still a considerable quantity of unchanged N-bromo-acetamide in the solution.

**N-Bromobenzamide.**—2 g. of this substance was dissolved in 100 cc. of hot benzene and 3.4 g. of mercury diphenyl dropped into the solution. It was then put out in the sunlight. After 20 minutes a considerable quantity of phenyl mercury bromide separated. The reaction, however, did not go to completion, as indicated by the presence of active bromine in the solution. To complete the reaction the solution was boiled on the water-bath for one hour longer. The precipitate (2.5 g.) was collected on a filter paper and identified as phenyl mercury bromide. To the filtrate aniline was added, and after 3 to 4 minutes a precipitate began to separate. It was allowed to stand for 20 minutes and the precipitate (0.8 g.) then collected on a filter paper, m. p. 231°. The melting point of symmetrical diphenyl urea given in the literature is 230°, mixed m. p. 230°.

<sup>12</sup> Throughout this investigation, only sodium-dried benzene was used.

<sup>13</sup> Since only small amounts of material were used throughout this investigation, it was thought advisable to solate the urea derivatives by treating the isocyanates in solution with aniline rather than the free isocyanates.

By working up the filtrate from symmetrical diphenyl urea some more phenyl mercury bromide, a little unchanged mercury diphenyl and also an appreciable quantity of the symmetrical diphenyl urea were obtained.

***m*-Nitro-*N*-Bromobenzamide.**—To 0.7 g. of *m*-nitro-*N*-bromobenzamide dissolved in 180 cc. of benzene 1 g. of mercury diphenyl was added. After 1 hour it still gave a positive test for active bromine, and the reaction was only complete after 2 <sup>3</sup>/<sub>4</sub> hours' boiling. The precipitate (0.4 g.) that separated was identified as phenyl mercury bromide. From the filtrate after the addition of aniline and then ligroin a yellow crystalline compound (0.3 g.) was obtained which was identified as *m*-nitro-carbanilide, m. p. 197°. This melting point is not lowered by mixing the compound with known *m*-nitro-carbanilide.

The filtrate from the urea when evaporated to dryness and then worked up yielded some more phenyl mercury bromide and also *m*-nitro-carbanilide.

*o*- And *p*-nitro-*N*-bromobenzamides were treated in the same way as the *meta* isomer. The time of heating was from 2 to 3 hours. When worked up like the *meta* compound they yielded phenyl mercury bromide and the corresponding nitro-carbanilides which were identified by their melting points.

### Action of *N*-Chloro-acetanilide on Various Compounds.

**Mercury Diphenyl.**—*N*-chloro-acetanilide (0.84 g.) was dissolved in 80 cc. of sodium-dried benzene and then 1.7 g. of mercury diphenyl added to it. The solution was then boiled for 14 hours, but even at the end of that time it still gave a strong test for active chlorine, and the mercury diphenyl was recovered by distilling the benzene *in vacuo*, and extracting the *N*-chloro-acetanilide with ligroin.

**Aniline.**—*N*-chloro-acetanilide (2 g.) was dissolved in 60 cc. of sodium-dried benzene and 0.6 g. of aniline added to it. The resulting solution was perfectly colorless, but turned dark after boiling it for 4 minutes. The reaction was complete in 20 minutes as indicated by the fact that the test for positive chlorine failed. Upon cooling a crystalline compound separated, (0.8 g.), which, after crystallization, melted at 114°. Its melting point was not lowered by mixing it with pure acetanilide.

To the filtrate from the acetanilide was added acetyl chloride to convert the dichloro-aniline into its acetyl derivative, and the mixture was warmed 10 minutes. The benzene solution was washed three times with water to destroy the excess of acetyl chloride, dried with sodium sulfate, and the benzene distilled. Crystals were thus obtained which upon crystallization melted at 146°. The melting point of 2,4-dichloro-aniline given in the literature is 147°; mixed m. p. 147°.

When dimethylaniline was used in place of aniline, acetanilide was also obtained and an oil, which was probably 2,4-dichloro-dimethylaniline. The latter compound is described in the literature as an oil.

### Summary.

1. It has been shown that the Hofmann Rearrangement takes place when various acyl halogen amides, in sodium-dried benzene, are treated with mercury diphenyl.

2. It has been demonstrated that mercury diphenyl acts as a base in benzene solution.

3. A convenient method for the preparation of isocyanates is described.

4. It has been pointed out that the structure,  $\text{R}-\overset{\text{---}}{\text{Hg}}-\overset{\text{---}}{\text{R}}$ , for mercury

diaryl compounds has no sound theoretical or experimental basis, and the structure  $\begin{smallmatrix} - & + & + & - \end{smallmatrix}$  R-Hg-R is supported.

5. It has been shown that N-chloro-acetanilide has no effect on mercury diphenyl, although it is a good chlorinating agent.

## MERCURI-ORGANIC DERIVATIVES. THE MERCURIZATION OF AROMATIC AMINES AND ITS RELATION TO THE THEORY OF SUBSTITUTION.

BY MORRIS S. KHARASCH<sup>1</sup> AND ISADORE M. JACOBSON.<sup>2</sup>

Received February 15, 1921.

The principles underlying the mercurization of aromatic compounds have occupied the attention of one of us (Kh.) for the past two years. The important fact that, in a mono-substituted benzene derivative, the mercury enters *para* or *ortho* to the group already present in the molecule, was pointed out early by Dimroth,<sup>3</sup> and has been substantiated by the vast amount of experimental work done by others. This fact of *ortho* and *para* substitution is particularly striking when one attempts to apply the theories of substitution to mercurization since mercury never enters *meta* to the group already present in the molecule. Even where the usual rules of substitution require that a *meta* derivative be formed, *e. g.*, with benzoic acid, benzophenone, and nitrobenzene, only *ortho* substituted mercury compounds have been isolated.

The phenomenon of mercurization was considered by Dimroth to be similar to that of nitration, sulfonation, etc., in the sense that the position taken by the entering mercury in compounds containing groups now considered electro-negative, *e. g.*, amino or hydroxyl groups, was quite in agreement with the rule of Crum Brown and Gibson. He considered the exceptional behavior of nitrobenzene, benzoic acid, and benzophenone as anomalous reactions which needed to be accounted for. However, until recently, no effort has been made to explain the orientation of mercury in the benzene molecule.<sup>4</sup> The rule of Crum Brown and Gibson, being purely empirical, offers no suggestion as to the mechanism of the

<sup>1</sup> National Research Fellow in Organic Chemistry.

<sup>2</sup> The material presented here is used by I. Jacobson in his dissertation presented in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the University of Chicago.

<sup>3</sup> Dimroth, *Ber.*, **35**, 2853 (1902).

<sup>4</sup> Schoeller, Schrauth, and Liese (*Ber.*, **52B**, 1777 (1919)) apply the theory of Armstrong for substitution in aromatic amines to mercurization, the limitations of which theory will be pointed out later.

reaction, nor does it help to predict whether a compound could be mercurized or not. Therefore, it appeared desirable to apply some of the modern theories of substitution to the orientation of mercury in the benzene molecule.

In the present paper, the authors will confine themselves to the mechanism of mercurization of aromatic amines and also attempt to show that the mechanism suggested for mercurization may be extended to explain satisfactorily orientation of other groups in the case of aromatic amines. It will be shown further, in a condensed critical survey of the theories of others, that none of these is completely satisfactory. For example, most of them fail to account for the fact that dimethylaniline is mercurized readily.

The theory which the present authors have been led to adopt as a result of their extended experimental work, briefly stated, is as follows. The mercurization of an aromatic amine proceeds in two stages: first, the formation of an ammonium salt with the mercuric acetate or chloride to give a compound of the general type I.

This compound is then rearranged to the more stable configuration having the mercury radical attached to carbon, (Type II), the *para* position being usually favored.<sup>5</sup> If this position is already occupied, the mercury goes to the *ortho* position. Furthermore, it is only the ammonium salt that undergoes rearrangement,<sup>6</sup> the instability of the salt being due to the presence of an electropositive group or atom on the amino nitrogen.<sup>7</sup>

This, it will be noted, is the application to mercurization of the theories of substitution of Armstrong,<sup>8</sup> Bamberger,<sup>9</sup> Chattaway<sup>10</sup> and others, and

<sup>5</sup> The fact of rearrangement may be due to a smaller energy content on the part of the rearranged compound. This relationship was shown to hold by Rother and Stoermer (*Ber.*, 46, 260 (1913)) for a number of compounds, *e. g.*, cinnamic acid and the isomeric allocinnamic acid.

<sup>6</sup> Acree and Johnson, *Am. Chem. J.*, 38, 265 (1905), have demonstrated that, in the rearrangement of N-chloro-acetanilide, it is the salt and not the free base that rearranges. They fail, however, to attach any importance to the positive charge on the rearranging group, a fact which has already been pointed out by Stieglitz and Stagner, *This Journal*, 38, 2057 (1916).

<sup>7</sup> Acree and Johnson, *Am. Chem. J.*, 38, 265 (1905), have shown that, when N-chloro-acetanilide is treated with hydrogen bromide, the speed of the rearrangement is a thousand times greater than when hydrogen chloride is used, and that the end product of the rearrangement is *p*-bromo-acetanilide, instead of *p*-chloro-acetanilide.

<sup>8</sup> Armstrong, *J. Chem. Soc.*, 51, 258, 583 (1887).

<sup>9</sup> Bamberger, *Ber.*, 27, 586 (1894).

<sup>10</sup> Chattaway, *J. Chem. Soc.*, 75, 1048 (1899).

of the general theory of catalysis advanced by Stieglitz,<sup>11</sup> Acree<sup>12</sup> and others that acid catalysts act through salt formation.<sup>13</sup> However, the theory advanced by the present authors diverges from that of Armstrong, Bamberger, and Chattaway, and also from recent theory of mercurization of Schoeller, Schrauth and Liese<sup>4</sup> in a few very important aspects. The theories advanced by the above mentioned authors assume that the entrance of a group into the nucleus of an aromatic amine is always preceded by substitution on the amino nitrogen, thus,

However, as an explanation, this is not adequate to account for the mechanism of substitution of tertiary amines, of the type of dimethyl aniline which contains no replaceable hydrogen. Furthermore, they do not emphasize the nature and importance of the catalysts used in substitution, *i. e.*, strong acids. That the rôle played by acid catalysts is that of salt formation has been pointed out very clearly by Stieglitz<sup>11</sup> in his work on the catalysis of imido-esters, as well as by Acree.<sup>12</sup>

We find thus, that the previous hypotheses have to be modified, if they are to explain consistently all the facts of substitution without further assumptions. The hypothesis advanced by the writers to explain the mercurization of aromatic amines lends itself admirably to this purpose. We shall now proceed to illustrate as briefly as possible the basis for this hypothesis and then show that it is quite compatible with the *ortho* and *para* orientation of other groups in the case of aromatic amines.

That mercury has a great affinity for amino nitrogen and for carbon is best illustrated by the readiness with which the mercury-ammonium complexes are formed, and by the great stability of mercury-carbon compounds.<sup>14</sup> It is the combination of this property of mercury to form stable nitrogen and carbon compounds, and the relatively greater stability of the latter, which enables us to attach mercury to the carbon of the benzene ring in the case of aromatic amines.

Within the scope of a series of investigations being carried out by the one of us, work was undertaken upon the mercurization of the N-alkylated

<sup>11</sup> Stieglitz, *Proc. Congress of Arts and Sci.* (St. Louis), IV, 278(1904); *Am. Chem. J.*, **39**, 29 (1908).

<sup>12</sup> Acree, *ibid.*, **37**, 410 (1907).

<sup>13</sup> In this connection, the work of Reilly and Hickinbotham (*J. Chem. Soc.*, **117**, 103 (1919)) on the rearrangement of *n*-butylaniline is quite significant. They found that only those salts which are capable of combining with the amino group effected the rearrangement.

<sup>14</sup> The stability of the mercury-carbon union is a relative term. It depends to a large extent upon the position of the mercury in the molecule and upon the nature of the neighboring groups. This will be discussed in a later paper. See also Stieglitz, Kharasch, and Hanke, *THIS JOURNAL*, **43**, 1186 (1921).

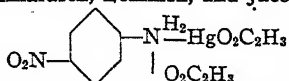

nitro-anilines. It was found that mercurization does not take place when *p*-nitro-dimethylaniline is treated with mercuric acetate in alcoholic solution. Though various experimental conditions were tried, the efforts were futile. It seemed, however, in view of the results of an investigation carried out with other nitro-anilines,<sup>15</sup> that mercurization should take place unless there was some property of the mercurizable nitro-anilines which was not shared by the *p*-nitro-dimethylaniline. Reference to the literature at once revealed the fact that *p*-nitro-dimethylaniline is an extraordinarily weak base. It is precipitated from even conc. hydrochloric acid solution as the free base instead of its hydrochloride, and it does not combine with chloroplatinic acid.<sup>16</sup> Further reference to the literature showed that its *ortho* and *meta* isomers form salts more readily. An investigation of the reactions of these isomers with mercuric acetate showed not only that the reactions are completed within a very short time but at a comparatively low temperature. An attempt was then made to mercurize *p*-nitro-diethylaniline. This met with the same failure as that of the corresponding dimethyl derivative. That this failure to mercurize is not due simply to the fact that the *para* position is occupied was then demonstrated by the fact that *p*-nitro-monomethyl- and *p*-nitro-mono-ethylanilines are mercurized without difficulty, the mercury being oriented to the position *ortho* to the amino group.

These facts, taken in conjunction with the intermediates already isolated<sup>17</sup> and those obtained by Schoeller, Schrauth and Liese,<sup>4</sup> the complex salts of aromatic amines isolated by Klein<sup>18</sup> and the known general fact of the great affinity of mercury for an amino nitrogen, led us to adopt the hypothesis that mercurization proceeds first by the addition of the mercury salt to the amino group, *i. e.*, to form an ammonium salt. This ammonium salt then rearranges to a compound in which the mercuric radical is attached to carbon.<sup>5</sup>

From this theory of the mechanism of mercurization, one of the most logical deductions to be made is that, *of the aromatic amines only those which are capable of forming salts will mercurize*. Among other tests, one to which this deduction has been put was an attempt to mercurize trimethyl-phenyl-ammonium acetate, a compound in which the formation of a double salt with the mercuric acetate used is impossible. This com-

<sup>15</sup> Unpublished work of Kharasch, Lommen, and Jacobsohn.

<sup>16</sup> We found, however, that a hydrochloride of *p*-nitro-dimethylaniline could be prepared by passing dry hydrogen chloride into a benzene solution of the base.

<sup>17</sup> Kharasch, Lommen, and Jacobsohn (unpublished work) have isolated the compound,  by treating an alcoholic solution of *m*-nitro-aniline with an aqueous solution of mercuric acetate.

<sup>18</sup> Klein, *Ber.*, 11, 743 (1878).

pound was not mercurized although a water suspension of dimethylaniline mercurizes within one or two minutes, with great evolution of heat.

The theory here advanced as to the mechanism of mercurization of aromatic amines adapts itself as already stated, quite readily to the explanation of the orientation of other groups upon substitution in the nucleus of aromatic amines.<sup>19</sup> Not only does it explain satisfactorily the cases of *ortho* and *para* substitution but, as will be shown later, it explains also the fact that a mixture of all three isomers is obtained when an aromatic amine is nitrated in conc. sulfuric acid solution, as well as the more recent observations of Vörländer<sup>20</sup> that, upon bromination and nitration, the quaternary ammonium salts yield only the *meta* derivative.

To explain these cases of *meta* substitution, Vorländer advances a theory of the benzene nucleus in which he assumes that the hydrogen atoms in the benzene molecule have positive tensions,<sup>21</sup> and that it is the tension within the nucleus which determines the position taken by the entering substituent. He assumes, further, that the nature of the tension on the group already substituted in the molecule exerts an influence on the arrangement of the tensions within the nucleus. Thus for nitrobenzene he assumes Structure I

while, for aniline, Structure II is assumed. Further, substitution takes place by absorption with the subsequent loss of a molecule of acid or water<sup>22</sup> thus:

<sup>19</sup> It is self-evident that this theory is applicable also to such rearrangements as those of hydrazobenzene, diazo-aminobenzene, the Fischer and Hepp, etc. It is to be noted, that, in all cases, where the rearranging compound is a weak base, the reaction must be carried out in anhydrous media to insure salt formation.

<sup>20</sup> Vorländer, *Ber.*, 52B, 263 (1919).

<sup>21</sup> In order to avoid committing himself to any theory as to the nature of valence, Vorländer uses the term "tension" and denotes the kind of tension by + and -. While he does not assume that they are electrical in nature, the properties assigned for them are such that, for the purpose of discussing substitution, there is little distinction to be made.

<sup>22</sup> It is rather peculiar that Vorländer does not take into account the fact that bromine is  $\text{Br}^+ - \text{Br}^-$ , unless by an error in print, since the existence of positive bromine has been proved conclusively. (W. A. Noyes, *THIS JOURNAL*, 23, 460 (1901); Stieglitz, *ibid.*, 23, 796 (1901); Walden, *Z. physik. Chem.*, 43, 385 (1903).

Vorländer makes the additional postulate, in order to explain the cases of *meta* substitution in aromatic amines, that, upon salt formation, there is a change in the tension throughout the molecule, *e. g.*, upon treating aniline with sulfuric acid, the following change is assumed to take place.

Such an assumption is entirely unwarranted. Not only are there no experimental facts upon which to base such an hypothesis, but the assumption made involves an upheaval taking place within the molecule, as well as a change of tension between the carbon and groups attached to it. Such a supposition as a change of tension would also demand that, in a compound such as aniline nitrate, analogous to aniline sulfate, the tension on the nitrogen bound to the phenyl group must be positive.

This compound should then, according to the views of Vorländer, give a *meta* derivative when dropped into conc. sulfuric acid. On the contrary, however, it gives only *o*- and *p*-nitro derivatives.<sup>23</sup> Similarly, the nitration of aromatic quaternary ammonium compounds demands, according to Vorländer, that the tension between the ammonium nitrogen and the carbon of the benzene nucleus be positive (II). This is hardly compatible with the fact that a water solution of the hydroxide of the compound (II) when evaporated gives a small quantity of trimethylamine and *m*-nitrophenol.<sup>24</sup> This theory must, therefore, be further modified if it is to be made to fit all the facts of substitution in aromatic amines.

Similarly, it has been necessary to make additional postulates to all previous theories in an attempt to build a workable theory of substitution. Yet, with all these postulates, none of the older theories can be made to fit all the facts of substitution. However, no new postulates need be made to the theory advanced by the present authors. Once it is assumed that all *ortho* and *para* substitution in the hydroquinoid nucleus of aromatic amines takes place through intermediate salt formation, it follows that, when such salt formation is impossible, as in the quaternary ammonium salts, substitution must take place in the *meta* position or, as in such special cases as that of mercurization, it is not accomplished at all.

<sup>23</sup> Bamberger, *Ber.*, 28, 400 (1895).

<sup>24</sup> Staedel and Bauer, *ibid.*, 19, 1939 (1885).

Not only does the theory advanced explain the case of *meta* substitution in the quaternary ammonium salts, but it explains also the fact that a mixture of all three isomers is obtained upon nitration of an aromatic amine in conc. sulfuric acid solution. It explains, further, the fact that the yield of the *meta* derivative increases with the amount of sulfuric acid used. Here it will be seen that an equilibrium mixture of both the amine and the ammonium salt exists in such a solution. Therefore, in such a mixture both types of substitution, that dependent upon intermediate compound formation, giving *ortho* and *para* derivatives, and the substitution of a salt yielding a *meta* derivative, are found. Again, as the volume of sulfuric acid is increased, the equilibrium will be shifted to form more of the sulfate, thus increasing the yield of the *meta* derivative.

Furthermore, the theory here advanced also offers an explanation of certain peculiar facts of rearrangement. For example, the rearrangement of  $\beta$ -phenyl-hydroxylamine<sup>25</sup> in alcoholic solution with hydrogen chloride as catalyst, gives not only *p*-amino phenetole but also *p*-chloro-aniline, the more strongly electro positive chlorine atom rearranging. The theory advanced predicts that N-substituted aromatic amines, when treated with a catalyst capable of being oxidized by the group already substituted in the molecule will yield a derivative having the more strongly electro positive group in the *para* position.

It will be seen, therefore, that the present theory explains from a single standpoint the rearrangement and substitution in the case of aromatic amines, without the necessity of any additional postulates. It is also far more adequate for the explanation of these facts and furnishes a more workable hypothesis than any of the other theories of substitution.

### Experimental Part.

#### Method used for Mercurization.

The method used for the preparation of the compounds herein described is, briefly, as follows. One mol of the compound to be mercurized was dissolved in a small volume of alcohol and boiled with an aqueous solution containing 0.9 mol of mercuric acetate, until a test portion gave no black precipitate of mercuric sulfide when treated with ammonium sulfide. This reaction mixture was filtered hot. Upon cooling, the acetate of the mercurized compound crystallized from the solution.

The filtrate from the above was treated with an aqueous solution of sodium chloride, whereupon the chloride of the mercury compound soon precipitated. The total yield of mercurized product calculated upon the basis of the mercuric acetate used, was almost quantitative.

An Attempt to Mercurize *p*-Nitro-dimethylaniline and *p*-Nitro-diethylaniline.—As stated in the theoretical part, several attempts were made to mercurize *p*-nitro-

<sup>25</sup> See, however, Stieglitz, *Am. Chem. J.*, 46, 327 (1911).

dimethylaniline, all of which met with failure. The method above outlined was used, as well as several other methods, none of which yielded a mercurized product. Similarly, attempts to mercurize *p*-nitro-diethylaniline were without success.

*o*-Nitro-*p*-Acetoxymercuri-dimethylaniline,  $(C_6H_5(1)N(CH_3)_2(2)NO_2(4)HgO_2C_2H_5)$ .—This compound was prepared from *o*-nitro-dimethylaniline and mercuricacetate. The reaction was completed after half an hour's boiling. The reaction mixture was filtered hot in order to remove the small amount of mercurous acetate formed in the reaction. It was then cooled and the precipitate collected on a filter. The precipitate was then washed with alcohol, and dried to constant weight *in vacuo* over sulfuric acid.

*Analyses.* Subs., 0.2759: dry  $N_2$ , 16.20 cc. (22° and 741 mm.). Subs., 0.2604:  $HgS$ , 0.1427. Calc. for  $C_{10}H_{12}O_4N_2Hg$ : N, 6.61;  $Hg$ , 47.23. Found: N, 6.63;  $Hg$ , 47.26.

The compound thus obtained is bright yellow; m. p. 160°. It is crystalline, and is soluble in the common organic solvents.

*o*-Nitro-*p*-Chloromercuri-dimethylaniline,  $(C_6H_5(1)N(CH_3)_2(2)NO_2(4)HgCl.H_2O)$ .—This compound was washed well with water to remove sodium chloride and finally with alcohol, and dried *in vacuo* over sulfuric acid to constant weight.

*Analyses.* Subs., 0.2635: dry  $N_2$ , 15.60 cc. (21.5° and 741 mm.). Subs., 0.3233:  $AgCl$ , 0.1096. Calc. for  $C_6H_5O_2N_2HgCl$ : N, 6.69;  $Cl$ , 8.46. Found: N, 6.71;  $Cl$ , 8.38.

The substance is red and amorphous. It is soluble in acetone and in boiling alcohol. It melts at 185°, with decomposition.

*m*-Nitro-*p*-Acetoxymercuri-dimethylaniline,  $(C_6H_5(1)N(CH_3)_2(3)NO_2(4)HgO_2C_2H_5)$ .—This preparation was obtained upon treating *m*-nitro-dimethylaniline with mercuric acetate. A half hour's boiling was sufficient to carry the reaction to completion. For analysis, the compound was dried to constant weight over sulfuric acid.

*Analyses.* Subs., 0.2924: dry  $N_2$ , 17.05 cc. (20° and 734 mm.). Subs., 0.2940:  $HgS$ , 0.1610. Calc. for  $C_{10}H_{12}O_4N_2Hg$ : N, 6.61;  $Hg$ , 47.23. Found: N, 6.56;  $Hg$ , 47.23.

The compound is obtained in the form of brilliant orange needles. It is soluble in the common organic solvents; m. p. 140°.

*m*-Nitro-*p*-Chloromercuri-dimethylaniline,  $(C_6H_5(1)N(CH_3)_2(3)NO_2(4)HgCl)$ .—This compound was obtained from the filtrate of the preceding preparation.

*Analysis.* Subs., 0.3438:  $AgCl$ , 0.1237. Calc. for  $C_6H_5O_2N_2HgCl$ :  $Cl$ , 8.84. Found: 8.90.

The compound is red and amorphous. It is soluble in acetone and in boiling alcohol. It melts at 220°, with decomposition.

*p*-Nitro-*o*-Acetoxymercuri-monomethylaniline,  $(C_6H_5(1)NH.CH_3(4)NO_2(2)HgO_2C_2H_5)$ .—This compound was prepared from *p*-nitro-methylaniline and mercuric acetate. The product obtained was extracted with ether in order to remove unchanged *p*-nitro-methylaniline, and the residue was recrystallized from alcohol. A dark red solid remained which was insoluble in alcohol, but the quantity was too small to be analyzed.

*Analyses.* Subs., 0.2585: dry  $N_2$ , 15.6 cc. (21° and 736 mm.). Subs., 0.2981:  $HgS$ , 0.1673. Calc. for  $C_9H_{10}O_4N_2Hg$ : N, 6.84;  $Hg$ , 48.82. Found: N, 6.79;  $Hg$ , 48.38.

The compound forms small yellow crystals melting at 197° with decomposition. It is soluble in acetone and in hot alcohol to which a few drops of glacial acetic acid have been added. When treated with a conc. potassium hydroxide solution, a brick-red compound is formed. Upon dilution, the compound again becomes yellow.

*p*-Nitro-*o*-Chloromercuri-monomethylaniline,  $(C_6H_3(1)N.H.CH_3(4)NO_2(2)HgCl.(H_2O))$ .—This compound is obtained from the filtrate of the preceding compound.

*Analysis.* Subs., 0.2972: AgCl, 0.1036. Calc. for  $C_7H_5O_2N_2HgCl$ : Cl, 8.75. Found: 8.62.

The compound is yellow and crystalline. It is soluble in acetone and in boiling alcohol. It melts at  $215^\circ$ , with decomposition.

The position of the mercury in this compound was determined by the method of Dimroth.<sup>26</sup> The acetate was treated with two equivalents of a solution of potassium permanganate. The product was then extracted with ether and the extract purified from alcohol; m. p.  $112-113^\circ$ . When mixed with 4-nitro-2,6-dibromo-monomethylaniline, prepared by the method of Blanksma,<sup>27</sup> the melting point was not lowered. The use of only one molecule of the bromine in solution yielded no definite compound. Since the position could not be thus in dispute the dibromo derivative was therefore isolated.

*p*-Nitro-*o*-Acetoxymmercuri-mono-ethylaniline,  $(C_6H_3(1)N.H.C_2H_5(4)NO_2(2)Hg.O_2.C_2H_3)$ .—This compound was prepared from *p*-nitro-mono-ethylaniline, and was purified from the unchanged raw material by recrystallization from alcohol.

*Analyses.* Subs., 0.2641: dry  $N_2$ , 15.7 cc. ( $24.5^\circ$  and 731 mm.). Subs., 0.3480:  $HgS$ , 0.1912. Calc., for  $C_{10}H_{12}O_4N_2Hg$ : N, 6.61; Hg, 47.23. Found: N, 6.56; Hg, 47.17.

It crystallizes from alcohol in small yellow crystals; m. p.  $183^\circ$ . It is also soluble in acetone. When treated with conc. potassium hydroxide solution, a brick-red compound is obtained. Dilution of the solution restored the original yellow color.

*p*-Nitro-*o*-Chloromercuri-mono-ethylaniline,  $(C_6H_3(1)N.H.C_2H_5(4)NO_2(2)HgCl.(H_2O))$ .—The compound was prepared in the usual manner. It is obtained in the form of an amorphous yellow solid; m. p.  $218^\circ$ , with decomposition. For analysis it was dried to constant weight over sulfuric acid.

*Analysis.* Subs., 0.4544: AgCl, 0.1573. Calc. for  $C_8H_{11}O_2N_2HgCl$ : Cl, 8.46; Found: 8.56.

It is soluble in acetone and in hot alcohol.

The position of the mercury in this compound was determined by the method used above for the corresponding methyl derivative. The melting point of the 4-nitro-2,6-dibromo-ethylaniline thus obtained was  $68-71^\circ$ . The melting point was not lowered when a mixture of the compound with known 4-nitro-2,6-dibromo-ethylaniline was used.

*p*-Nitro-*o*-Bromo-mono-ethylaniline,  $(C_6H_3(1)N.H.C_2H_5Br(4)NO_2)$ .—This compound was prepared by the addition of a solution of bromine in glacial acetic acid to a solution of an equivalent portion of *p*-nitro-mono-ethylaniline in the same solvent. After standing for about half an hour, the reaction mixture was diluted with water, and the precipitated compound collected on a filter. It was washed with water and a little alcohol. After crystallization from alcohol, the compound was dried to constant weight *in vacuo*. Yield, 90%.

*Analysis.* Subs., 0.2704: dry  $N_2$ , 26.50 cc. ( $17^\circ$  and 750 mm.). Calc. for  $C_8H_9O_2N_2Br$ : N, 11.44. Found: 11.39.

The compound crystallized from alcohol in beautiful long yellow prisms which are highly refractive; m. p.  $65^\circ$  to  $66^\circ$ . It is insoluble in water but soluble in all common organic solvents.

When an alcoholic solution of the compound is treated with conc. potassium hydroxide solution, the alcoholic layer assumes a red color. Upon evaporation of the alcohol, or upon dilution with water, the yellow compound is again obtained.

<sup>26</sup> Dimroth, *Ber.*, 35, 2033 (1902).

<sup>27</sup> Blanksma, *Rec. trav. chem.*, 31, 271 (1902).

*p*-Nitro-*o*-Dibromo-mono-ethylaniline,  $(C_6H_5(1)N.H.C_2H_5(2,6)Br_2(4)NO_2)$ .—This compound was prepared in the same manner as the above monobromo derivative, in this case, with two mols of bromine. For analysis the compound was crystallized from alcohol. Yield, 90%.

*Analysis.* Subs., 0.2761: dry  $N_2$ , 21.2 cc. ( $21^\circ$  and 744 mm.). Calc. for  $C_8H_8O_2N_2Br_2$ : N, 8.68. Found: N, 8.74.

This compound crystallized from alcohol in small yellow needles; m. p.  $75-76^\circ$ . It is insoluble in water, but soluble in all common organic solvents.

Upon treatment with a conc. potassium hydroxide solution, an alcoholic solution of the compound turns red. If the alcohol is evaporated, or the solution diluted with water, the color is restored to the original yellow.

*An Attempt to Mercurize Trimethyl-phenyl-ammonium Acetate.*—A solution of 0.5 mol of mercuric acetate was added to a solution of trimethyl-phenyl-ammonium acetate. Even after standing for two months at room temperature, no mercurized product could be isolated. The solution gave a heavy precipitate of mercuric sulfide when treated with hydrogen sulfide.

Upon boiling another portion of the solution for 24 hours, no change was observed. A heavy precipitate of mercuric sulfide was again obtained upon treatment with hydrogen sulfide.

### Summary.

1. A theory of the mercurization of aromatic amines has been advanced, postulating that mercurization is preceded by addition of a mercuric salt to the amino nitrogen, with the subsequent rearrangement of the mercury to the *ortho* or *para* position. This theory, without any additional postulates, has been shown to apply equally well to the introduction of other groups in the benzene nucleus in the case of aromatic amines.

2. This theory has been shown to apply also to rearrangements such as that of Fischer and Hepp, the nitro-amines, sulfamic acids, etc.

3. The limitations to other theories of substitution have been pointed out.

4. The preparation of mercury derivatives of *p*-nitro-methylaniline, *p*-nitro-ethylaniline, *o*-nitro-dimethylaniline, and *m*-nitro-dimethylaniline, and the preparation of *o*-bromo and *o,o*-dibromo-*p*-nitro-ethylanilines have been described.

## BENZYL ETHERS OF CARBOHYDRATES.

BY M. GOMBERG AND C. C. BUCHLER.

Received May 16, 1921.

In a previous communication<sup>1</sup> it was shown that benzyl esters could be prepared in good yields, and a pure condition, from benzyl chloride and the sodium salt of the corresponding acid dissolved in water; in aqueous solution, also, benzyl ethers, amines, benzonitriles, etc., were prepared. In testing further the applicability of this method of procedure, we have now studied the action of benzyl chloride upon carbohydrates.

Alkylation of carbohydrates had been limited for a time, since 1893, to E. Fischer's<sup>2</sup> method of making alkyl glucosides by the condensation of the carbohydrate and the alcohol through the agency of hydrochloric acid. Under these circumstances, the alkyl group becomes attached to the oxygen in the aldehydic or ketonic group, and can be readily separated by hydrolysis. Later, Maquenne<sup>3</sup> prepared  $\beta$ -methylglucoside by the action of methyl sulfate and sodium hydroxide on glucose. Purdie and Irvine<sup>4</sup> then showed that the hydrogen atoms in the four alcoholic hydroxyl groups also could be replaced by alkyl groups by the use of silver oxide and alkyl iodide. As was to be expected, the resulting ethers are not subject to the influence of hydrolyzing agents under ordinary conditions, and consequently they exceed greatly in stability the esters of the carbohydrates. Irvine and his co-workers have successfully methylated in this way a number of carbohydrates, partial alkylation occurring readily and complete alkylation being achieved by repeated treatment in several stages. The use of methyl sulfate for making methyl ethers of cellulose was described by Denham and Woodhouse in 1913.<sup>5</sup> In the same and in the following year appeared brief abstracts of patented processes<sup>6</sup> for methyl and ethyl cellulose ethers, using alkyl sulfates or halides. More recently Haworth<sup>7</sup> showed that not only cellulose, but various sugars can be alkylated through the agency of methyl sulfate and aqueous sodium hydroxide instead of the expensive materials as in the method of Purdie and Irvine. Since then, the methyl sulfate procedure alone, or that and followed by the more drastic treatment with methyl iodide and silver oxide, has been used by

Denham and Woodhouse<sup>8</sup> on cellulose, by Haworth<sup>9</sup> on maltose and on cellobiose, by Irvine<sup>10</sup> on inulin, and by Karrer<sup>11</sup> on starch.

In addition there are several more recent patents.<sup>12</sup> All these patents make, of course, very broad claims for alkylating agents in general, but mention of specific examples is limited, so far as we are aware, to examples of methyl and ethyl ethers only, from cellulose and from starch. Benzyl ethers specifically we find mentioned only in Brit. pat. 149,320, "for carbohydrates of the general formula  $C_6H_{10}O_5$ ;" the abstract of this patent came into our hands after all the work described in this paper had been completed. Here, again, the working example described in this last patent is that of ethyl ethers.

Benzyl chloride, we find, lends itself exceedingly well to the alkylation of all classes of carbohydrates. No attempt was made for the present to ascertain the best conditions for the most complete alkylation, but merely to determine how general this reaction is. Methylglucoside, sucrose, lactose, inulin, dextrin, starch and cellulose all form benzyl ethers more or less readily. The general procedure was to dissolve, or suspend, the individual carbohydrate in water which contained enough sodium hydroxide to keep the solution alkaline throughout the whole period of reaction; benzyl chloride was added in the proportion of slightly more than 1 mol of the chloride for each hydroxyl group in the carbohydrate used, and the mixture well stirred. After the reaction was deemed to have been completed, the excess of benzyl chloride was removed by steam distillation, and the subsequent treatment was as described below, for the individual carbohydrates. For analysis, the purified products were dried at 100° for 6 to 10 hours.

### Experimental.

**Benzylation of Glucose.**—Several preliminary experiments with glucose gave unsatisfactory results, due no doubt to the detrimental action of the alkali upon the glucose.  $\alpha$ -Methylglucoside was then prepared by the method of E. Fischer, except that we used much less methyl alcohol and the latter contained only 10% of hydrogen chloride instead of being saturated with it. The glucose solution was allowed to stand until it ceased to reduce Fehling's solution, and a 50% yield of  $\alpha$ -methylglucoside was obtained.

When the glucoside was benzylated at 85° to 90°, an oil was obtained which was insoluble in water but soluble in benzene. The results of the

elementary analysis indicate that this must have been a mixture consisting largely of dibenzyl-methylglucoside with some higher benzylated products. The following procedure was employed in the separation of the reaction mixture into its components.

9.7 g. (1 mol) of methylglucoside, 12 g. (6 mols) of sodium hydroxide in 100 cc. of water, and 27.5 g. (4.4 mols) of benzyl chloride were heated with stirring at 90° to 95° for 6 hours. The excess of benzyl chloride was removed by steam distillation, the aqueous solution was decanted from the oily reaction product and worked up separately. The oil was then stirred up with 4 successive portions of 100 cc. each of hot water, in order to dissolve out any benzyl alcohol that might have been present. The residue was taken up in benzene, the solution dried with calcium chloride and the solvent completely removed. The oily product was then extracted several times with petroleum ether, b. p. 50° to 70°, which dissolved out about half of the material. On evaporation of the petroleum ether 1.5 g. of residue of a mobile consistency was obtained, which proved to be the completely benzylated product, tetrabenzyl-benzylglucoside. (II). The portion which did not dissolve in petroleum ether, also about 1.5 g., became a stiff paste, as it cooled. It proved to be dibenzyl-methylglucoside. (I).

*Analyses* I. Calc. for  $C_{17}H_{24}O_6(C_7H_7)_2$ : C, 67.37; H, 6.95. Found: C, 67.07; H, 6.81.

II. Calc. for  $C_{26}H_{34}O_6(C_7H_7)_5$ : C, 78.10; H, 6.65. Found: C, 78.25; H, 6.78.

The aqueous solution decanted from the mixture of the insoluble benzylated glucosides was examined for the presence of water-soluble products, and was found to contain 2.5 g. of unchanged methylglucoside, and 2 g. of benzylglucoside. The aqueous solution, after neutralization, was evaporated to dryness, extracted with 95% alcohol, the filtered alcoholic solution evaporated to dryness and again extracted with absolute alcohol; the latter was evaporated to dryness. The residual mixture was washed with benzene in order to remove any benzyl alcohol, and the two glucosides were separated from each other by means of acetone, which dissolved only the benzylglucoside and left behind a white crystalline mass, readily identified as the methylglucoside by its melting point, solubilities and composition. The product soluble in acetone was analyzed with the following result.

*Analysis*: Calc. for  $C_8H_{14}O_6(C_7H_7)$ : C, 57.78; H, 6.67. Found: C, 56.71; H, 6.89.

Thus, under the conditions described, the action of benzyl chloride upon methylglucoside yielded three products: benzylglucoside, dibenzyl-methylglucoside and tetrabenzyl-benzylglucoside.

The benzylglucoside showed the properties described for this compound by E. Fischer<sup>13</sup> who prepared it from benzyl alcohol and glucose. It was characterized by a bitter taste and was found to be soluble in water, alcohol, benzene, chloroform, ethyl acetate and acetone; insoluble in ether and in petroleum ether. It did not reduce Fehling's solution, but was readily hydrolyzed by 8% hydrochloric acid upon boiling the solution, and gave rise to a strongly reducing carbohydrate; it was soluble in conc. hydrochloric acid and was hydrolyzed by it in the cold.

The substance of the composition of dibenzyl-methylglucoside was a semi-solid material, soluble in benzene and chloroform; it gave a cloudy

<sup>13</sup> Fischer, *Ber.*, 26, 2410 (1893).

solution with acetone and with ethyl acetate, was only slightly soluble in alcohol and in acetic acid, and insoluble in absolute ether and in petroleum ether. It was found to be without effect upon Fehling's solution; upon boiling with 8% hydrochloric acid for 1 hour it yielded a product still only little soluble in water, but strongly reducing.

Tetrabenzyl-benzylglucoside is the completely benzylated product. Assuming the usually accepted butylene oxide formula for the glucosides, the constitution of the benzylated product is,

This substance is an oil, as is the completely methylated  $\alpha$ -methyl-glucoside,<sup>14</sup> and is soluble in a greater variety of organic solvents than the partially benzylated compound, being soluble even in ether and in petroleum ether. It is not reducing, but becomes so upon boiling for an hour with dil. hydrochloric acid. In cold conc. hydrochloric acid it remains largely undissolved, and only after two days' standing does the solution show appreciable action upon Fehling's reagent.

**Benzylation of Sucrose.**—It was found difficult to judge the progress of the reaction in the case of sucrose, since the resulting products remain dissolved in the excess of the benzyl chloride.

One mol of sucrose, 8.8 mols of benzyl chloride and 12 mols of sodium hydroxide (10%) were heated for 4.5 hours at 85°. After steam distillation the residual gum was dissolved in a mixture of chloroform and benzene, the solution dried, and absolute ether added to the concentrated solution. The precipitated granular powder was rubbed up with fresh quantities of absolute ether, filtered, washed and dried. Analysis showed that the substance was a mixture of the monobenzyl derivative with higher alkylated products. In the next run, with materials in the same proportion as above, the heating was done at 100° for 3 hours and the reaction mixture was worked up in the same manner. The product consisted almost wholly of dibenzyl sucrose, containing 58.2% of carbon, and 6.1% of hydrogen. In the next experiment the action was more drastic. The mixture was heated for 4 hours at 100°, the aqueous layer was siphoned off and to the oil fresh benzyl chloride and sodium hydroxide solution were added. After further heating for 4 hours the mixture was worked up as described. There were no water-soluble benzyl sucroses formed; those insoluble in water were dissolved in chloroform. After evaporating all the chloroform the crude gummy product was resolved, on treatment with absolute ether, into two components: an insoluble white granular solid which proved to be dibenzyl sucrose, and a portion soluble in ether, an oil, which analyzed for a pentabenzyl sucrose. This oil, before analysis, was extracted several times with petroleum ether in order to remove any benzyl alcohol that might, perhaps, be present.

**Analyses.** Solid. Calc. for  $\text{C}_{12}\text{H}_{20}\text{O}_{11}(\text{C}_7\text{H}_7)_2$ ; C, 59.77; H, 6.51. Found: C, 59.73; H, 6.14.

Liquid. Calc. for  $\text{C}_{12}\text{H}_{17}\text{O}_{11}(\text{C}_7\text{H}_7)_5$ ; C, 71.21; H, 6.56. Found: C, 70.09; H, 6.53.

<sup>14</sup> Purdie and Irvine, *J. Chem. Soc.*, 83, 1080 (1903).

The dibenzyl and the pentabenzyl sucrose possess a most persistent bitter taste. Although they are practically insoluble in water, yet the supernatant aqueous layer acquires in a short time the intensely bitter taste. Neither of these compounds reduces Fehling's solution. On boiling with 8% hydrochloric acid small amounts of the substances are hydrolyzed and the solutions acquire reducing properties. In cold conc. hydrochloric acid the benzyl compounds dissolve partially. The solutions become dark colored and after 2 to 3 hours' standing show reducing properties, the dibenzyl derivative apparently hydrolyzing more readily than the pentabenzyl. The two compounds were found to be soluble in alcohol, acetic acid, chloroform, chlorohydrin, ethyl acetate, benzene, and nitrobenzene. The pentabenzyl was soluble also in ether and in acetone, while the dibenzyl sucrose was only slightly soluble in acetone and not at all in ether. Both were found to be insoluble in petroleum ether.

The benzyl sucroses furnish excellent examples of the influence of the benzyl group upon the physiological properties of substances. It is generally recognized that, in a substance possessing sweet taste, the entrance of a phenyl<sup>15</sup> or benzyl group into the molecule tends to decrease the sweetness, and it often inverts the taste completely from the sweet to the bitter. Methyl- and ethylglucosides,  $\alpha$ - and  $\beta$ -modifications, as well as the similar glucosides of other monoses, are all sweet; but with increase in weight of the alcohol molecule the taste begins to change, and the glucosides of benzyl alcohol, benzaldehyde, salicyl alcohol, of phenols—synthetic and natural glucosidic products—are in the great majority of instances bitter. Now, in the benzyl sucroses here described, the benzyl group can not be linked to an aldehydic or ketonic oxygen, since none such is present in sucrose, and yet these benzyl ethers compare well with quinine or picric acid in taste.

**Benzyl Dextrin.**—The dextrin used was a product known to have come from pure potato starch and was completely soluble in water.

One mol of dextrin, 3.5 mols of benzyl chloride and 4.5 mols of sodium hydroxide (9%), were heated at 80° to 85° for 4 hours, and treated in the usual manner. Upon addition of ether to the concentrated chloroform solution of the reaction mixture, from 16 g. of dextrin 18 gr. of the insoluble benzyl derivative was obtained. Elementary analysis gave results for carbon only slightly in excess of that required for a substance of the formula  $C_{12}H_{19}O_{10}C_7H_7$ . The benzyl compound obtained was a white amorphous tasteless powder, melting at about 208–10°. It was insoluble in water, acetone, ether; slightly soluble in benzene, and nitrobenzene. It swelled up in alcohol and ethyl acetate and with chloroform, chlorohydrin, and acetic acid gave colloidal transparent solutions which passed through filter paper with difficulty. It did not reduce Fehling's solution, was slowly hydrolyzed by dil. hot hydrochloric acid, or when in contact with the cold concentrated acid.

<sup>15</sup> G. Cohn, "Organische Geschmackstoffe," Franz Siemenroth, 1914, pp. 102, 243–266.

**Benzylation of Starch.**—The experiments were performed on two samples of starch of known origin, potato and corn starch. In each case the reaction temperature was  $85^{\circ}$  to  $90^{\circ}$ , the relative proportions of the reacting ingredients were the same as with dextrin, and yet the resulting products were not alike: potato starch took up one benzyl group for each  $C_{12}$  molecule, while corn starch took up two benzyl groups.

The crude gummy reaction product from potato starch, after thorough air drying, was dissolved in chlorohydrin, and the solution was diluted with chloroform and filtered through paper in a jacketed funnel. The benzyl compound was precipitated from its solution by the addition of ether, and the white powder was rubbed up in a mortar with several portions of fresh ether, filtered and dried. The yield was 8 g. of the powder from 8 g. of starch. The corn starch gave a crude product similar in appearance to that obtained from the potato starch. It was divided into portions: one portion was purified by solution in chlorohydrin and precipitation therefrom by means of ether, the second portion by solution in acetic acid and reprecipitation by ether. The yield was 20 g. of the benzyl compound from 16 g. of the corn starch.

*Analyses.* Potato starch. Calc. for  $C_{12}H_{19}O_{10}(C_7H_7)$ : C, 55.07; H, 6.28. Found: C, 55.85; H, 6.12.

Corn starch (chlorohydrin). Calc. for  $C_{12}H_{18}O_{10}(C_7H_7)_2$ : C, 61.92; H, 6.35. Found: C, 61.38; H, 6.38.

Corn starch (acetic acid). Calc. for  $C_{12}H_{18}O_{10}(C_7H_7)_2$ : C, 61.92; H, 6.35. Found: C, 60.43; H, 6.31.

The monobenzyl starch melted at  $200^{\circ}$  to  $203^{\circ}$ , the dibenzyl at  $203^{\circ}$  to  $205^{\circ}$ . Both were soluble in chlorohydrin and acetic acid, and insoluble in alcohol, acetone, ether, chloroform, benzene, nitrobenzene, ethyl acetate and benzyl benzoate. Filter paper, dipped into a solution of the benzyl starch becomes tough and water-proof when dry. With Fehling's solution the benzyl starches behave like benzyl dextrin.

**Inulin**, also, was benzylated in like manner as the starches, and the resulting product analyzed a little short for a substance of the formula  $C_{12}H_{19}O_{10}(C_7H_7)$ .

**Benzylation of Cellulose.**—Cellulose, unless previously subjected to one of the several so called "hydration" processes, was found to suffer but slight benzylation under the conditions as described for the other carbohydrates. It was found that benzylated cellulose was insoluble in Schweitzer's reagent, and this fact greatly facilitated the purification of the alkylated products.

(1) Absorbent cotton, subjected to previous hydration by means of zinc chloride and hydrochloric acid and, of course, carefully freed from these, was benzylated in the usual manner at  $90^{\circ}$  to  $95^{\circ}$ . The resulting product was still partially soluble in cuprammonium solution, and the elementary analysis indicated an extent of benzylation less than one benzyl group for each  $C_{12}$  molecule.

(2) Five g. of absorbent cotton was dissolved in Schweitzer's reagent and the solution allowed to stand overnight. The cellulose was precipitated by the addition of alcohol, and was thoroughly freed from copper. It was then digested for 12 hours with a solution of sodium hydroxide (11 g. of alkali in 73 cc. of water); 22 g. of benzyl chloride was added and the mixture was heated for 7 hours at  $90^{\circ}$  to  $95^{\circ}$ . After steam distillation, the product was thoroughly washed with water, alcohol and ether. The gray powder was then insoluble in cuprammonium solution, in chloroform, chlorohydrin, acetone, acetic acid, benzene and nitrobenzene.

*Analysis.* Calc. for  $C_{12}H_{19}O_{10}(C_7H_7)$ : C, 55.07; H, 6.28. Found: C, 54.34; H, 6.24.

(3) Five g. of absorbent cotton was converted into hydrocellulose by means of hydrogen chloride.<sup>16</sup> After completely washing out the acid from it, the material was digested for 3 hours with 50 cc. of 15% sodium hydroxide solution; then 10 cc. of water and 18 g. of benzyl chloride were added and the mixture was heated for 4 hours. The benzylated product was digested for several hours with cuprammonium solution, filtered, washed, digested in several changes of dil. hydrochloric acid, and washed with water, alcohol and ether. The benzylated product, amounting to 4 g., consisted of white very short fibres. Hydrocellulose is generally assumed to be a further degradation product of cellulose than the "cellulose hydrates." The composition of hydrocellulose is given as  $n(C_6H_{10}O_5) + H_2O$ ,  $n$  varying from 2 to 6,<sup>17</sup> and this relative composition is believed to be retained in the various derivatives of hydrocellulose.<sup>18</sup> For our purposes we may assume  $n$  equal to 4 and shall not be far from the truth.

*Analysis.* Calc. for  $2C_{12}H_{19}O_{10}(C_7H_7) \cdot H_2O$ : C, 53.90; H, 6.38. Found: C, 53.60; H, 6.58.

(4) Absorbent cotton was soaked in a 15% sodium hydroxide solution for 3 days, and then squeezed until the cotton retained about 3 times its weight of the alkaline solution. The alkali cellulose was heated for 5 hours at 100° with an excess of benzyl chloride. After steam distillation and preliminary purification, the product was digested for 2 days with cuprammonium solution and then purified as described above. Throughout the whole treatment the fibrous structure of the cotton was retained.

*Analysis.* Calc. for  $C_{12}H_{19}O_{10}(C_7H_7)$ : C, 55.07; H, 6.28. Found: C, 57.97; H, 6.37.

(5) More homogeneous products were obtained with filter-paper cellulose. Four g. of pure ashless paper, cut into small pieces, was soaked for 12 hours in 30 cc. of 20% sodium hydroxide solution; 45 cc. of water was then added and the mixture was heated for an hour at 90° to 95° with no apparent change. Seventeen g. of benzyl chloride was introduced and the heating continued. After 4 hours the paper began to change visibly, gathering into a clump. After another hour of heating, the mixture was worked up in the usual way, digested for a day in Schweitzer's reagent and purified.

*Analysis.* Calc. for  $C_{12}H_{19}O_{10}(C_7H_7)$ : C, 55.07; H, 6.28. Found: C, 55.38; H, 6.45.

(6) Filter-paper cellulose was subjected to a more energetic, two-stage, benzylation. Five g. of the paper was digested for 2 days at room temperature in a solution of 10 g. of sodium hydroxide in 30 cc. of water, 30 g. of benzyl chloride was added and the mixture was heated at 100° for 7 hours. After distillation with steam and thorough washing with water, alcohol and ether, the dried material weighed 6 g. A portion of this was saved for purposes of analysis, and the remaining 4.5 g. was subjected once more to the same treatment with alkali and benzyl chloride. It yielded, after washing with alcohol and ether, 5 g. of dry product which however proved to be not entirely homogeneous. On digestion with ethyl acetate most of it, but not all, went into solution and was reprecipitated from the clear filtrate, upon the addition of absolute alcohol, as a white, horny substance. The one-stage benzylated product was treated, before analysis, with cuprammonium solution.

*Analyses.* One-stage benzylation. Calculated for  $C_{12}H_{17}O_{10}(C_7H_7)_3$ : C, 66.67; H, 6.39. Found: C, 66.10; H, 6.41.

<sup>16</sup> Cross and Bevan, "Cellulose," Longmans Green and Co., 1918, pp. 54, 254.

<sup>17</sup> Meyer u. Jacobson, "Organische Chemie," Veit and Co., 1913, I, 2, p. 1044.

<sup>18</sup> Worden, "Technology of Cellulose Esters," Van Nostrand Co., 1916, VIII, p. 2541.

Two-stage benzylation. Calculated for  $C_{12}H_{16}O_{10}(C_7H_7)_4$ : C, 70.17; H, 6.58. Found: C, 69.74; H, 6.32.

It does not appear probable that the product showing the composition of tribenzyl cellulose is a mixture of di- and tetrabenzyl derivatives. The mono benzyl compound did not show signs of softening when heated to  $250^\circ$ , the tribenzyl substance melted at  $208^\circ$  to  $10^\circ$ , while the tetra benzyl compound softened at  $165^\circ$ , and melted at  $175^\circ$  to  $77^\circ$ . The tribenzyl substance appeared as fully insoluble in the various organic solvents as the monobenzyl derivative, while the tetrabenzyl cellulose proved soluble in chlorohydrin, chloroform, nitrobenzene, ethyl acetate, and was gelatinized by acetone.

The three benzyl derivatives do not reduce Fehling's solution. On treating with dilute acid, the monobenzyl and the tribenzyl compounds yield after 1 hour soluble reducing carbohydrates, while tetrabenzyl cellulose does not do so even after two hours' heating. None of the three substances is soluble in cold conc. hydrochloric acid, and the latter contains no reducing carbohydrates after 2 hours' contact with the products, and shows but a slight reduction after two days' standing.

#### Summary.

It has been shown that carbohydrates of all types are readily benzylated, and various benzyl ethers obtained are described. The benzylation reaction should prove useful in the further study of carbohydrates, just as alkylation by means of methyl sulfate has proven so preëminently fruitful in this field. Moreover, some of the benzyl ethers of the carbohydrates may prove, it is hoped, technically useful products because of their properties as colloid and plastic substances, particularly since benzyl chloride is relatively inexpensive and the group increases considerably the molecular weights of the carbohydrates to which it adds.

### THE QUANTITATIVE DETERMINATION OF PHENANTHRENE.<sup>1</sup>

BY ARTHUR G. WILLIAMS.\*

Received May 16, 1921.

The hydrocarbon phenanthrene has been the object of much research. It occurs in relative abundance in coal tar along with carbazole and anthracene, being isomeric with the latter. Much work has naturally been directed toward using it in making dyes and, indeed, many patents have been granted for dyes of which it forms a basis. Notable among such dyes is flavinduline. Further, the morphine alkaloids contain a phenanthrene nucleus, and this fact has been most potent in giving impulse to investiga-

<sup>1</sup> Read before the Dye Division of the American Chemical Society at the Rochester Meeting, April, 1921.

\* Died September 1, 1921.

tion of the chemistry of the hydrocarbon and of its derivatives. It will be clear that an adequate method of determining it is desirable.

In spite of the fact that the constituents of coal tar have interested chemists for many years past, there are comparatively few of these constituents for which accurate quantitative methods have been worked out,—methods comparable to that for anthracene, for example, and applicable in the presence of the usual accompanying substances. Thus we are still compelled to determine carbazole by first removing bases, then determining the remaining nitrogen and calculating it as carbazole. For naphthalene there is no chemical method at all comparable to that for anthracene, though the chemistry of the former early reached a high state of development. Highly accurate methods of determination then are almost everywhere lacking among the coal-tar constituents, even including benzene and toluene. It is not surprising, therefore, that for phenanthrene, which has only just begun to receive commercial development in this country, there should have been wanting an adequate mode of quantitative estimation.

**Historical.**—Record of essentially but one method of analysis appears in the literature.<sup>2</sup> In one variation the hydrocarbon is precipitated as the picrate from an alcoholic solution. The phenanthrene is then regenerated and washed with sulfuric acid to remove acridine. Allowance is made for the phenanthrene picrate remaining dissolved in the mother liquors. In the other variation<sup>3</sup> the hydrocarbon is precipitated as the picrate from xylene solution. An allowance is made for the amount of "rough picrate" remaining dissolved in the xylene mother liquor. A weighed portion of the precipitated "rough picrate" from the xylene is then recrystallized from 95% alcohol and a correction (20 g. of picrate for 750 cc. of 95% alcohol) applied in order to allow for the picrate remaining dissolved in the alcoholic mother liquors.

Küster<sup>4</sup> attempted the estimation of phenanthrene by conversion to the picrate by means of an aqueous solution of picric acid, but without success.

Obviously any attempt to determine phenanthrene by means of picric acid in the presence of the usual coal-tar accompaniments is seriously handicapped by two factors, (1) the relatively large solubility corrections that have to be applied, and (2) the fact that the most important anthracene-oil accompaniments of phenanthrene also form picrates of about the same order of solubility. Thus, for example, anthracene, carbazole, and fluorene all form picrates.

**Analysis of the Problem.**—The problem resolved itself, in view of the recorded chemistry of the compound, into (1) the quantitative oxidation of the hydrocarbon to the quinone, and (2) the quantitative estimation of the quinone produced.

<sup>2</sup> Anschütz and Schultz, *Ann.*, 196, 43 (1879).

<sup>3</sup> Lunge's "Coal Tar and Ammonia," Pub. D. Van Nostrand Co., 4th Ed., 1916, p. 643.

<sup>4</sup> Küster, *Ber.*, 27, 1104 (1894).

It was found convenient to solve the second part of the problem first in order to make it easy to follow progress in working out the first part.

### Experimental.

**Quantitative Determination of Phenanthraquinone.**—For this second aspect of the problem a solution lay already in view inasmuch as phenanthraquinone, as an *ortho*-diketone, forms generally well defined, rather insoluble compounds, azines, with *ortho*-diamines. 3,4-tolylene diamine was chosen as precipitant both because it forms with phenanthraquinone a well defined, sufficiently insoluble azine,<sup>5</sup> toluphenanthrazine, and because it is an easily obtainable *ortho*-diamine.<sup>6</sup> Moreover, the precipitation takes place very well in glacial acetic acid and since it was proposed to carry out the oxidation of phenanthrene also in glacial acetic solution, this fact was of great assistance. To be carried out, therefore, in connection with the second aspect of the problem, there remained for the most part only the obtaining of quantitative data regarding the precipitation, data by means of which progress in much of the search for a quantitative oxidant was followed.

*Experiment 1.*—One-fourth g. of phenanthraquinone (m. p. 203°) was dissolved in 25 cc. of glacial acetic acid. To the cold solution 0.60 g. of 3,4-tolylene-diamine was added. After standing in running tap water overnight, the precipitated toluphenanthrazine was filtered on a weighed Gooch crucible and washed with water. Yield, 0.3043 g., or 86.1%; m. p., 217° (uncorr.).

*Experiment 2.*—Another experiment in which only 0.28 g. of base was added and where the system stood in tap water only 30 to 40 min. resulted in a yield of 0.2979 g. of precipitate, or 84.5%. The precipitate was washed in this case, first with 50% acetic solution and then with water.

*Experiment 3.*—A third experiment was carried out as follows. 0.2500 g. of the quinone was dissolved in 25 cc. of glacial acetic acid in a 50cc. Erlenmeyer flask. 0.7407 g. of iodic acid (the oxidant for phenanthrene later found most suitable) was added and the solution was boiled under an air condenser for 2½ hours. No free iodine appeared. After standing overnight in tap water, the solution was filtered through a Gooch crucible into another Erlenmeyer flask and the residue of iodic acid washed with glacial acetic acid. Inasmuch as a slight sediment appeared in the filtrate (perhaps asbestos from the filter mat), the solution was distilled to less than 25 cc., then made up to 25 cc. and allowed to stand in running tap water overnight. The solution was again filtered, distilled to less than 25 cc. and made up again to 25 cc. 0.60 g. of base was added and, after standing in running tap water overnight, the precipitate was filtered off. It weighed 0.3026 g. an 85.6% yield; m. p., 215.5° to 216.6° (uncorr.).

The average yield in these three experiments is 85.4%, but 85.0% was taken for subsequent calculations as being within the experimental error in practical application. The theoretical weight of toluphenanthrazine from 0.2500 g. of phenanthraquinone is 0.3535 g. The solu-

<sup>5</sup> Hinsherg, *Ber.*, 18, 1228 (1885); *Ann.*, 237, 341 (1887).

<sup>6</sup> Gattermann, *Ber.*, 18, 1483 (1885); Kleemann, *ibid.*, 19, 336 (1886); Beilstein and Kuhlberg, *Ann.*, 158, 351 (1871).

bility of toluphenanthrazine in 25 cc. of glacial acetic acid is, for practical purposes, represented by  $(100 - 85 =) 15\%$  of 0.3535 g., or 0.0530 g. This latter weight, then, since precipitation was always performed in 25 cc. of solution, was always added as a correction to the weight of the azine precipitated.

The three experiments described above further indicate that the amount of base added is without material influence on the result and that iodic acid does not destroy phenanthraquinone under the conditions.

Another base, 1-ethoxy-3,4-diaminobenzene<sup>7</sup> was later tried and found to precipitate 91.3% of 0.2500 g. of phenanthraquinone under conditions as above described. Washing in this case was first performed with 25 cc. of a 50% acetic acid solution saturated with *p*-ethoxy-phenanthrazine,<sup>8</sup> the product precipitated, and finally with water. This diamine was not further experimented with, however, inasmuch as considerable data were already at hand based on the use of 3,4-tolylenediamine.

**The Quantitative Oxidation of Phenanthrene.**—Many substances were tried in the course of the search for a quantitative oxidant for phenanthrene. Among the substances which, judging in some cases only by the appearance of yellow color, resulted in the formation of phenanthraquinone when boiled with a glacial acetic acid solution of phenanthrene, were lead dioxide, manganese dioxide (upon the addition of a few cubic centimeters of 1-1 sulfuric acid), hydrogen peroxide, potassium chlorate, potassium bromate, potassium iodate, and iodic acid. Chromic acid was not experimented with since it is known to have a destructive action on phenanthraquinone. The search finally narrowed down to the potassium halates and from these to iodic acid, which alone was found to be suitable. Potassium bromate was found to be much quicker in action than iodic acid but it also had a destructive effect on phenanthraquinone. For example, after boiling a solution of 0.2500 g. of the quinone in 25 cc. of glacial acetic acid for 2½ hours with 0.80 g. of potassium bromate, but 59.7% of the quinone was precipitable as toluphenanthrazine.

Experiments according to the Höchst test with iodic acid were carried out using a sample of phenanthrene (A) containing 8.4% of anthracene<sup>9</sup> and no doubt other impurities, although it was a pure white material of excellent appearance. In each of these experiments a solution of 0.2500 g. of the hydrocarbon in 25 cc. of glacial acetic acid, contained in a 50cc. Erlenmeyer flask, was boiled with 0.74 g. of iodic acid under an air condenser for the time specified. Each flask was then allowed to stand in running tapwater overnight, after which the excess of iodic acid

<sup>7</sup> Autenrieth and Hinsberg, *Arch. Pharm.*, **229**, 456 (1891).

<sup>8</sup> Autenrieth and Hinsberg, *Ber.*, **25**, 497 (1892).

<sup>9</sup> Essentially as described in Lunge's "Chem.-tech. Untersuchungsmethoden," Julius Springer, Berlin, 4th Edition, Vol. II, p. 740.

was filtered through a Gooch crucible (mat dry, or wet with acetic acid) into another Erlenmeyer flask (a 100cc. flask is most conveniently used) and washed with glacial acetic acid. The filtrate was evaporated to slightly less than 25 cc. and then made up to exactly 25 cc. by comparison with a similar flask containing 25 cc. of water. When the contents of the flask were cool, 0.60 g. of the base was added. After standing overnight, the precipitate was filtered on a weighed Gooch crucible and washed first with 25 cc. of 50% acetic acid and then with water. The solubility correction of 0.0530 g. was added in each case and the percentage of phenanthrene calculated. The factor for the conversion of toluphenanthrazine to phenanthrene is 0.6052.

The results of five experiments are tabulated as follows.

Expt.	Boiling time. Hours.	Wt. of precipitate. G.	Phenanthrene indicated. %.	Remarks.
4	0.5	0.0838	33.1	m. p. of ppt. 213.5°. (uncorr.)
5	2.0	0.2927	83.7	m. p. of ppt. 213°-213.5°. (uncorr.)
6	2.5	0.2949	84.2	
7	2.5 or 3.5	0.2958	84.4	Boiling time probably 2½ hrs.
8	3.0	0.2924	83.6	

The results of four similar experiments with a much purer phenanthrene, (B), melting at 99.6° follow. They differ only in that 0.75 g. of iodic acid and 1.00 g. of base were used and in that the 50% acetic acid wash solution was saturated with toluphenanthrazine, variations having little or no effect on the results.

Expt.	Boiling time. Hours.	Wt. of precipitate. G.	Phenanthrene indicated. %.
9	2.5	0.3359	94.1
10	2.5	0.3367	94.2
11	3.0	0.3356	94.1
12	3.75	0.3352	94.0

The preceding nine experiments, together with Expt. 3, show that phenanthraquinone in acetic acid solution is not attacked by iodic acid and they indicate that 2½ hours' boiling results in a quantitative oxidation of the phenanthrene, inasmuch as longer boiling times do not cause any further alteration in the phenanthrene content found.

That a quantitative oxidation of phenanthrene had been attained was further shown by the results of analyses of mixtures of the 84.2% phenanthrene (A), with a high purity anthracene (C), with an anthracene of lower grade (D), and with an analyzed crude phenanthrene (E). Sample C melted at 216° and analyzed 97.05% anthracene; Sample D was a technical product of 88.7% purity, and Sample E analyzed 68.4% phenanthrene (see Expts. 18 and 19). The following tabulation and remarks present the results of these experiments and detail any varia-

tions in procedure. The duration of oxidation in each experiment was  $2\frac{1}{2}$  hours. 0.60 g. of base was used each time.

Expt.	Composition of sample.	Wt. of $\text{HIO}_3$ . G.	Wt. of precipitate. G.	Phenanthrene. Found. %.	Calc. %.
13	0.2500 g. of Anth. C +0.2500 g. of Phen. A	1.5	0.2744	39.6	42.1
14	"	1.5	0.2771	39.9 <sup>a</sup>	42.1
15	0.8000 g. of Anth. C +0.2000 g. of Phen. A	2.0	0.2110	16.0 <sup>a</sup>	16.8
16	0.1250 g. of Anth. D +0.1250 g. of Phen. A	0.75	0.1348	45.5	42.1 + x
17	0.1250 g. of Phen. E +0.1250 g. of Phen. A	0.75	0.2634	76.6	76.3

<sup>a</sup> The somewhat low results may indicate the desirability of longer oxidation time in the case of materials high in anthracene.

REMARKS.—*Expts. 13, 14, and 15:* Oxidized in 50 cc. of glacial acetic acid; let stand 48 hours in running water; filtered off precipitated anthraquinone, washing with glacial acetic acid; distilled to 20 cc.; let stand overnight in running water; filtered off slight brownish deposit of impure anthraquinone, washed with glacial acetic acid; distilled to 25 cc.; cooled; added base; let stand overnight in running water.

*Expt. 16:* Oxidized in 25 cc. of glacial acetic acid; let stand overnight in running water; filtered off the precipitated anthraquinone, washing with glacial acetic acid; distilled to about 18 cc.; let stand overnight in running water; filtered, washing with glacial acetic acid; distilled to 25 cc.; cooled; added base; let stand in running water overnight.  $x = \%$  of phenanthrene from Sample D, doubtless not more than a few per cent.

*Expt. 17:* Similar to 16 except that there was but one distillation.

Anthracene also is oxidized to the quinone by iodic acid, hence the necessity of the procedure followed in the preceding five experiments directed toward removing anthraquinone. This separation is possible because of the very considerably lower solubility of anthraquinone in glacial acetic acid as compared with phenanthraquinone.

Both potassium bromate and iodic acid in glacial acetic acid are excellent oxidants for anthracene. Boiling 0.2500 g. of a 97.0% anthracene in 25 cc. of glacial acetic acid for 5 minutes with 0.70 g. of potassium bromate resulted in an oxidation of 74.1% of the anthracene. Boiling 1.0000 g. in 50 cc. for 20 minutes with 2.5 g. of potassium bromate resulted in an oxidation of 92.8% and 89.8% (2 samples). Boiling 1.0000 g. in 50 cc. for  $2\frac{1}{2}$  hours with 3.00 g. of iodic acid resulted in an oxidation of 98.4% and 98.3% of the anthracene (2 samples). Following oxidation, the determination of the anthraquinone produced was accomplished as in the Höchst procedure for anthracene. Potassium bromate and iodic acid are probably quantitative oxidants for this hydrocarbon.

**Examples of Application of the Method.**—The phenanthrene was determined on three specimens of crude phenanthrene. The first was the material (E) referred to above, the second (F) was essentially the

phenanthrene fraction from a column distillation (plant scale) of an anthracene oil and was an oily solid, while the third (G) was the press-cake obtained from Sample F by pressing in a letter-press between folds of filter paper. 0.60 g. of base and 0.74 g. of iodic acid were used in each determination.

Expt.	Material. G.	Wt. of precipitate. G.	Phenanthrene. %.
18	0.2500 (E)	0.2290	68.26
19	"	0.2304	68.61
20	0.2500 (F)	0.2097	60.8
21	"	0.2151	61.9
22	0.2500 (G)	0.2643	76.8
23	"	0.2589	75.5

REMARKS.—*Expts. 18 and 19:* Oxidized in 25 cc. glacial acetic acid; cooled; filtered, washing with glacial acetic acid; distilled to 25 cc.; cooled; added base; let stand overnight; filtered, washed with 25 cc. of 50% acetic acid saturated with toluphenanthrazine, and with water.

*Expts. 20 and 21:* Oxidized in 20 cc. of glacial acetic acid; let stand overnight; filtered, washed with glacial acetic acid; distilled to 18–20 cc.; let stand overnight; filtered, washed with glacial acetic acid; distilled to 25 cc.; cooled; added base; finished as for No. 18.

*Expt. No. 22:* Same as for Expts. 20 and 21, except that material received but one distillation.

*Expt. No. 23:* Same as for Expts. 20 and 21.

In the hands of two other persons, Sample F gave the following results: 60.8%, 58.4%, average 59.6%; 61.2%, 60.3%, average 60.8%. These results represented their first experience with the method.

**Material Suited to Analysis.**—The method of analysis for phenanthrene employed in the preceding experiments is, in general, suitable for mixtures of anthracene-oil hydrocarbons 30% or higher in phenanthrene, containing less than 10% of carbazole, and containing no large amounts of the anthracene-oil constituents boiling above 360°. Cruder material requires preparation directed toward lowering the carbazole content and toward removing the high-boiling constituents. The method is best suited for crude and refined phenanthrenes and phenanthraquinones. It has been applied with satisfactory results directly to the phenanthrene range of distillates from a plant column distillation of anthracene oil.

Carbazole, if present in amounts exceeding perhaps 10%, interferes in the determination of phenanthrene. An oxidation product apparently is formed. This product is colored and behaves rather like a quinone. It will be further investigated. Fluorene does not interfere since it is not attacked. Acenaphthene, also, does not interfere because the quinone, if formed, gives a rather soluble azine. Moreover, acenaphthene is not likely to occur in any considerable proportion along with phenanthrene. In any event, the two hydrocarbons can be separated by distillation. Some

of the high-boiling coal-tar constituents interfere and a crude anthracene cannot be directly analyzed. Anthracene does not interfere since the anthraquinone formed may be filtered off from a smaller volume than that in which it is intended to precipitate the phenanthraquinone.

### Formal Analytical Procedure.

For materials containing 30% or more of phenanthrene, weigh out a 0.2500g. sample into a 50cc. Erlenmeyer flask. Add 0.75 g. of iodic acid and 20 cc. of glacial acetic acid. Fit a plain 90cm. air condenser to the flask and boil for  $2\frac{1}{2}$  hours at such a rate that the ring of iodine which usually condenses in the tube stands about 60 cm. from the flask. Cool, preferably for several hours, especially if anthraquinone separates, and then filter with gentle suction into a 100cc. Erlenmeyer flask through a Gooch crucible. A glass filter funnel (so-called carbon filter) is best used to hold the crucible. The oxidation mixture should be so slowly poured into the crucible that only a minimum amount of wash liquid need be used. Wash with glacial acetic acid. Fit the flask to a small empty Hempel distilling tube and distil to a volume *slightly* less than 25 cc. Some iodine will be carried over. By treating a portion of the distillate with a sodium thiosulfate solution, the color of the iodine may be removed in order to obtain assurance that no quinone has been carried over. Remove the Erlenmeyer flask and while the liquid is still warm make the volume (by comparison) up to 25 cc., as exactly as possible, with glacial acetic acid. Cool. Add 1.00 g. of 3,4-tolylene-diamine and swirl the flask until it has dissolved. A darkening, due to the action of iodine, will occur when the diamine is added. Set the flask in running water (at about 20°) overnight. Filter through a weighed Gooch crucible, using 25 cc. of a 50% glacial acetic acid solution saturated with toluphenanthrazine in transferring the precipitate and in the first part of the washing on the filter. Finally, wash with 200 cc. of cold water, dry the precipitate, and weigh. To the weight of the toluphenanthrazine add 0.0530 g., the weight of toluphenanthrazine remaining dissolved in the mother liquor. Multiply the sum by 0.6052, the factor for the conversion of toluphenanthrazine to phenanthrene, and calculate the percentage of the latter.

If the anthracene content exceeds a certain percentage (probably not under 15%, but perhaps considerably higher) anthraquinone may crystallize on cooling after oxidation. This will not interfere unless it is necessary to use so much acetic acid for washing that enough anthraquinone is dissolved to come down again when the volume is reduced to 25 cc. If, following distillation, it should crystallize out on cooling and making the volume up to 25 cc., further distillation to about 20 cc., cooling, refiltration, redistillation, etc., will be necessary.

With certain materials low in phenanthrene, it is practicable to weigh out 0.5000g. samples and oxidize in 50 cc. of glacial acetic acid with 1.50 g. of iodic acid. In such cases, the first distillation is carried to less than 25 cc. and the solution is allowed to cool and stand. It is then filtered again, distilled, etc., and precipitation is performed in 25 cc., as usual.

### The Qualitative Determination of Phenanthrene.

Phenanthrene may be very conveniently determined qualitatively in the following manner. Oxidize the material to be tested as for quantitative determination. Cool; filter; pour the filtrate into water; filter; wash with water. Warm the residue with conc. sodium hydrogen sulfite solution. Filter and transfer the filtrate to a small separatory funnel. Wash with one or two portions of carbon tetrachloride to remove any accompanying hydrocarbons. Add a small portion of fresh carbon tetrachloride and acidify with hydrochloric acid containing ferric chloride to prevent the reduction of the liberated phenanthraquinone. Collect the quinone in the carbon tetrachloride and, first drying the spout of the funnel, draw off the carbon tetrachloride, which contains the quinone, and test by the reaction of Hilpert and Wolf.<sup>10</sup> The solution of the quinone is heated to boiling and there are added a few drops of a solution of 1 volume of antimony pentachloride in 2 volumes of carbon tetrachloride. A purple-red precipitate indicates phenanthraquinone and hence phenanthrene. Anthraquinone, which gives a cinnabar-red color with this reagent, cannot interfere because it would not be present, nor can acenaphthenequinone because it gives an apple-green precipitate. Fluorenone, which gives an orange precipitate, turning to reddish-orange, also would not be present.

### Summary.

Phenanthrene may be determined quantitatively by oxidation in glacial acetic acid by means of iodic acid to phenanthraquinone followed by precipitation of the quinone produced by means of 3,4-tolylene-diamine.

A procedure for the qualitative detection of phenanthrene is described.

NEW YORK, N. Y.

**FRIEDEL AND CRAFTS' REACTION. THE CARBOMETHOXY-BENZOYL CHLORIDES WITH AROMATIC HYDROCARBONS AND ALUMINUM CHLORIDE.**

BY MAURICE E. SMITH.

Received May 18, 1921.

Roser<sup>1</sup> obtained the amyl ester of benzoyl-formic acid from the acid chloride of mono-amyl oxalate, benzene and aluminum chloride. This preparation suggested the use of the acid chlorides of the mono-alkyl esters of the phthalic acids for the preparation of various keto acids.

The isophthalic acid and the terephthalic acid were prepared by the oxidation of commercial xylene, which had been fractionated with a 150cm. column, by Professor Kenrick in this laboratory. It was found that the fraction boiling at 138.2° to 138.4° gave the largest yield of terephthalic acid.

**Oxidation of the Xylene.**—Fifty g. of xylene, b. p. 138.2° to 138.4°, 5 liters of water and 30 g. of sodium hydroxide were heated to 90° in a 10-liter can which had a tight-fitting cover containing openings for condenser, mechanical stirrer and thermometer. All the openings were made steam tight. To the mixture was added 300 g. of potassium permanganate in 4 equal portions at half-hour intervals. After 19 hours' heating at 85° to 95° the solution was decolorized with methyl alcohol, cooled, filtered and the filtrate acidified. The precipitate dried at 110° weighed 60 g.

**Separation of the Acids.**—This product was found to be practically free from phthalic acid which is soluble 0.58 g. in 100 g. of water at 20°. The isophthalic acid and terephthalic acid were separated by means of their barium salts. The solubility of barium terephthalate and barium isophthalate, determined by evaporating a saturated solution and drying the residue at 200° for 8 hours, was found to be approximately 0.5 g. and 14.0 g. respectively in 100 g. of water at 20°. Fittig<sup>2</sup> using this method boiled the acids with barium carbonate but this is not convenient when using large quantities.

Sixty g. of the mixed acids was made into a paste with water and warmed with 125 cc. of conc. ammonia on a water-bath for 20 minutes; more water was then added to dissolve the ammonium salts, and the solution was boiled to expel the excess of ammonia. When nearly neutral, the volume was made up to 350 cc. and a hot solution of 40 g. of barium chloride in 70 cc. water added. After shaking for one hour and standing for 12 hours the barium terephthalate was filtered off, washed, and digested on a water-bath for 6 hours with 100 cc. of 15 % hydrochloric acid; yield

<sup>1</sup> Roser, *Ber.*, 14, 940 (1881).

<sup>2</sup> Fittig, *Ann.*, 153, 269 (1870).

of terephthalic acid 11.5 g. The combined filtrates were acidified affording 47 g. of isophthalic acid.

Further purification of the acids was effected by recrystallization of the dimethyl esters. Twenty g. of isophthalic acid and 150 cc. of methyl alcohol saturated with hydrogen chloride on standing for 36 hours gave 19 g. of dimethyl isophthalate, m. p.  $66^{\circ}$  to  $67^{\circ}$ . Ten g. of terephthalic acid boiled for 7 hours with 150 cc. of methyl alcohol and 15 cc. of conc. sulfuric acid gave 8 g. of dimethyl terephthalate, m. p.  $141^{\circ}$ .

***o*-Carbomethoxy-benzoyl Chloride with Benzene and Aluminum Chloride.**—Six g. of *o*-carbomethoxy-benzoyl chloride was dissolved in 80 cc. of benzene, cooled to  $10^{\circ}$ , and 10 g. of aluminum chloride added gradually with shaking. After standing for one hour at room temperature the mixture was kept at  $80^{\circ}$  for 7 hours and then poured into 100 cc. of 10% hydrochloric acid. After distilling off the benzene the ester was hydrolyzed with alcoholic potassium hydroxide, water was added and the solution was acidified with hydrochloric acid. The precipitate when recrystallized from ethyl alcohol gave 4.7 g. of *o*-benzoylbenzoic acid.

***m*-Carbomethoxyl-benzoyl Chloride with Benzene and Aluminum Chloride.**—Five g. of *m*-carbomethoxy-benzoyl chloride was dissolved in 90 cc. of benzene and 9 g. of aluminum chloride added. The mixture was kept at  $45^{\circ}$  to  $50^{\circ}$  for 5 hours and then at  $80^{\circ}$  for 7 hours. After hydrolysis of the ester and recrystallization from dilute alcohol the yield of *m*-benzoyl-benzoic acid, m. p.  $161$ – $162^{\circ}$ , was 3.9 g.

Silver salt. Calc. for  $C_{14}H_9O_3Ag$ : Ag, 32.4. Found: 31.9.

This acid had previously been prepared by Doebner<sup>3</sup> from benzoic anhydride, benzoyl chloride and zinc chloride, by Ador<sup>4</sup> as a by-product in the preparation of isophthalophenone, and by Senff<sup>5</sup> who oxidized benzyl-toluol. None of these methods give nearly as good a yield as was obtained above.

***p*-Carbomethoxy-benzoyl Chloride with Benzene and Aluminum Chloride.**—Five g. of *p*-carbomethoxy-benzoyl chloride, 50 cc. of benzene and 8.5 g. of aluminum chloride were heated at  $45^{\circ}$  to  $50^{\circ}$  for 5 hours and then on a boiling water-bath for 5 hours. After hydrolysis of the ester the *p*-benzoyl-benzoic acid was separated from terephthalic acid by dissolving in alcohol and recrystallized by the addition of water, m. p.  $194^{\circ}$ ; yield, 4 g; terephthalic acid recovered, 2 g.

One g. of the acid dissolved in thionyl chloride and added to methyl alcohol gave after recrystallization from methyl alcohol 1 g. of methyl *p*-benzoyl-benzoate, m. p.  $106$ – $107^{\circ}$ .

<sup>3</sup>Doebner, *Ber.*, 14, 647 (1881).

<sup>4</sup>Ador, *ibid.*, 13, 320 (1880).

<sup>5</sup>Senff, *Ann.*, 220, 236 (1883).

***o*-Carbomethoxy-benzoyl Chloride with Toluene and Aluminum Chloride.**—Five g. of *o*-carbomethoxy-benzoyl chloride, 50cc. toluene, and 8.5 g. of aluminum chloride were heated at 45° to 50° for 5 hours and then on a boiling water-bath for 7 hours. After addition of hydrochloric acid and removal of the toluene the reaction product was separated by the addition of ether, hydrolyzed with alcoholic potassium hydroxide and recrystallized from dil. alcohol, m. p. 96–100°; dried in a vacuum at 80°, m. p. 138° to 40°. The acid was fused with potassium hydroxide for 20 minutes at 200° and gave a mixture of benzoic acid and *p*-toluic acid. As it was not easy to separate these acids the mixture was boiled for 3 hours with alkaline permanganate solution, acidified and the product esterified with methyl alcohol. The ester recrystallized from alcohol melted at 140°. This identifies it as dimethyl terephthalate and identifies the product of hydrolysis as *p*-toluic acid. The original acid is, therefore, *p*-toluyl-*o*-benzoic acid. This acid has been prepared from phthalic anhydride, toluene and aluminum chloride by Limpricht<sup>6</sup> and others.

***m*-Carbomethoxy-benzoyl Chloride with Toluene and Aluminum Chloride.**—Five g. of *m*-carbomethoxy-benzoyl chloride was dissolved in 60 cc. of benzene and, after cooling the solution to 10°, 9 g. of aluminum chloride was added gradually. After standing at room temperature for one hour, the mixture was heated on a water-bath for 10 hours. The product was hydrolyzed with alcoholic potassium hydroxide and the acid obtained was recrystallized from hot methyl alcohol. Yield, 4.0 g.; m. p. 172°.

Silver salt. Calc. for  $C_{15}H_{11}O_3Ag$ : Ag, 31.1. Found: 30.8.

On fusion with potassium hydroxide and oxidation of the acid product with potassium permanganate, terephthalic acid, identified by its methyl ester, was obtained. The method of preparation and the product of hydrolysis identify the product of this reaction as *p*-toluyl-*m*-benzoic acid, not previously described.

One g. of *p*-toluyl-*m*-benzoic acid was dissolved in thionyl chloride, the excess of thionyl chloride removed and 25 cc. of methyl alcohol added. After the reaction ceased the solution was poured into cold water and the ester recrystallized from methyl alcohol, m. p. 108°. Yield of methyl *p*-toluyl-*m*-benzoate, 0.9 g.

***p*-Carbomethoxy-benzoyl Chloride with Toluene and Aluminum Chloride.**—Five g. of *p*-carbomethoxy-benzoyl chloride, 60 cc. of toluene, and 9 g. of aluminum chloride were heated for 9 hours at 40–50° and then for 2 hours on a boiling water-bath. After washing the reaction product with dil. sodium hydrogen carbonate solution, it was hydrolyzed with alcoholic potassium hydroxide and the acid recrystallized from methyl alcohol; m. p. 228°; yield 4.4 g. The methyl ester was prepared; m. p.

<sup>6</sup> Limpricht, *Ann.*, 299, 300 (1898).

126°. *p*-Toluyyl-*p*-benzoic acid had previously been prepared by Limp-richt<sup>7</sup> by oxidizing *p,p*-ditolyl ketone.

*o*-Carbomethoxy-benzoyl Chloride with *m*-xylene and Aluminum Chloride.—Five g. of *o*-carbomethoxy-benzoyl chloride and 50 cc. of *m*-xylene were cooled to 10° and 8.5 g. of aluminum chloride was added gradually. After the initial reaction had ceased the mixture was warmed on a water-bath until hydrogen chloride ceased to come off. After acidification and removal of the *m*-xylene the reaction product was extracted with chloroform, hydrolyzed with alcoholic potassium hydroxide and recrystallized from benzene as fine needles; m. p. 139–140°; yield, 3.5 g.

Silver salt. Calc. for  $C_{16}H_{13}O_3Ag$ : Ag, 29.9. Found: 30.2.

On fusion of the acid with potassium hydroxide for 30 minutes at 160° to 170°, and sublimation of the acid product, benzoic acid and 2,4-dimethyl-benzoic acid, m. p. 124° to 126°, were identified. The acid is therefore 2,4-dimethyl-benzoyl-*o*-benzoic acid and is identical with the acid prepared by Meyer<sup>8</sup> from phthalic anhydride, *m*-xylene and aluminum chloride. Meyer gave no melting point.

*m*-Carbomethoxy-benzoyl Chloride with *m*-xylene and Aluminum Chloride.—Five g. of *m*-carbomethoxy-benzoyl chloride, 40 cc. of *m*-xylene and 8.5 g. of aluminum chloride were kept at 20° for 5 hours and then on a boiling water-bath for 6 hours. After acidification and removal of the *m*-xylene the reaction product was extracted with chloroform, washed with dil. sodium hydrogen carbonate solution, hydrolyzed with alcoholic potassium hydroxide and acidified; yield of crude acid, 6.0 g. Recrystallized from hot methyl alcohol the acid melted at 168°; yield, 4.0 g.

Silver salt. Calc. for  $C_{16}H_{13}O_3Ag$ : Ag, 29.9. Found: 30.0.

On fusion of the acid with potassium hydroxide for 20 minutes at 170° to 80° and sublimation of the acid products the sublimate contained benzoic acid and 2,4-dimethyl-benzoic acid, m. p. 126°, and the residue from the sublimation was isophthalic acid, identified by the formation of its methyl ester. The greater part of the acid decomposes into isophthalic acid and *m*-xylene, but part of it gives benzoic acid and 2,4-dimethyl-benzoic acid. The acid is, therefore, 2,4-dimethyl-benzoyl-*m*-benzoic acid.

One g. of 2,4-dimethyl-benzoyl-*m*-benzoic acid was warmed with thionyl chloride until the reaction ceased and the resulting acid chloride was poured into methyl alcohol. The ester was precipitated by adding water and recrystallized from methyl alcohol, giving small needles; m. p. 73°.

*p*-Carbomethoxy-benzoyl Chloride with *m*-xylene and Aluminum Chloride.—Five g. of *p*-carbomethoxy-benzoyl chloride, 40 cc. of *m*-

<sup>7</sup> Limpriht, *Ann.*, 312, 92 (1900).

<sup>8</sup> Meyer, *Ber.*, 15, 636 (1882).

xylene and 8.5 g. of aluminum chloride were kept at 45° to 50° for 5 hours and then at 80° for 7 hours. The acid product was obtained as in the previous experiment and after recrystallization from methyl alcohol melted at 184° to 5°; yield, 4.5 g.

Silver salt. Calc.  $C_{16}H_{12}O_2Ag$ : Ag, 29.9. Found: 30.0.

Fusion with potassium hydroxide gave benzoic acid, 2,4-dimethylbenzoic acid, and terephthalic acid, identified by the formation of its dimethyl ester. In this case, again, part of the acid decomposed to benzoic acid and 2,4-dimethylbenzoic acid and part to *m*-xylene and terephthalic acid. The acid is, therefore, 2,4-dimethylbenzoyl-*p*-benzoic acid.

The methyl ester of 2,4-dimethylbenzoyl-*p*-benzoic acid prepared from the acid chloride by adding methyl alcohol and recrystallizing from methyl alcohol was obtained as long, colorless needles; m. p. 59°.

### Summary.

1. A method has been described of preparing isophthalic acid and terephthalic acid from commercial xylene.

2. The reaction of each of the carbomethoxy-benzoyl chlorides with aluminum chloride and benzene, toluene, and *m*-xylene, respectively, has been studied. In each case, the reaction with toluene takes place in the *para* position to the methyl group, and with *m*-xylene in the *para* position to one of the methyl groups.

3. New and improved methods of preparing *m*-benzoylbenzoic acid, *p*-benzoylbenzoic acid and some of their derivatives have been given.

4. The following new compounds have been prepared: *p*-toluyl-*m*-benzoic acid, m. p., 172°; methyl-*p*-toluyl-*m*-benzoate, m. p., 108°; 2,4-dimethylbenzoyl-*m*-benzoic acid, m. p. 168°; methyl-2,4-dimethylbenzoyl-*m*-benzoate, m. p. 73°; 2,4-dimethylbenzoyl-*p*-benzoic acid, m. p. 185°; methyl-2,4-dimethylbenzoyl-*p*-benzoate, m. p. 59°.

This research was made under the direction of Professor F. B. Allan.

## THE INFLUENCE OF POTASSIUM HYDROXIDE ON THE FORMATION OF VINYL ALCOHOL FROM ACETALDEHYDE.

BY WILLIAM LLOYD EVANS AND CLOYD D. LOOKER.

Received May 23, 1921.

When ethyl alcohol<sup>1</sup> and acetaldehyde<sup>2</sup> are oxidized by means of potassium permanganate in the presence of potassium hydroxide, acetic, oxalic and carbonic acids are obtained. The amount of the oxalic acid formed in the oxidation of these organic compounds has been found to be proportional to the concentration of the potassium hydroxide used and also to the temperature employed. In the absence of any added alkali no oxalic acid is formed with either ethyl alcohol or acetaldehyde.

Since acetates are unattacked by solutions of alkaline permanganate under the conditions surrounding these experiments, it was assumed with Nef,<sup>3</sup> Denis,<sup>4</sup> McLeod<sup>5</sup> and others that the intermediate formation of vinyl alcohol was necessary in order to offer a satisfactory explanation for the presence of oxalic acid and carbon dioxide; that is, the acetaldehyde is enolized in accordance with the following equation.

Then the vinyl alcohol so formed would be oxidized to glycollic aldehyde,

which is in turn itself oxidized to oxalic acid and carbon dioxide.<sup>6</sup> A consideration of these facts seems to show that the alkali present in these oxidations must affect the production of vinyl alcohol molecules from acetaldehyde.

Nef<sup>3</sup> found that basic mercuric vinylate  $((\text{CH}_2=\text{CHO})_2\text{Hg}.\text{HgO})$  was formed from an aqueous solution of acetaldehyde and sodium carbonate in the presence of freshly precipitated mercuric oxide. McLeod<sup>5</sup> has observed that no vinyl alcohol is present in an alkaline solution of acetaldehyde if the concentration of the alkali is less than 0.10%; i. e., only acetic acid would be formed by the oxidation of acetaldehyde at alkali concentrations lower than this value. Furthermore, no oxalic acid or carbon dioxide would be formed under these conditions. From the work of Evans and Day<sup>7</sup> and Evans and Adkins<sup>8</sup> it has been shown that the maximum concentration of alkali at which ethyl alcohol and

<sup>1</sup> THIS JOURNAL, 38, 375 (1916); 41, 1267 (1919).

<sup>2</sup> *Ibid.*, 41, 1385 (1919).

<sup>3</sup> Nef, *Ann.*, 298, 315 (1897).

<sup>4</sup> Denis, *Am. Chem. J.*, 38, 568 (1907).

<sup>5</sup> McLeod, *ibid.*, 37, 25 (1907).

<sup>6</sup> THIS JOURNAL, 41, 1280, 1397 (1919).

<sup>7</sup> Evans and Day, *ibid.*, 41, 1282 (1919).

<sup>8</sup> Evans and Adkins, *ibid.*, 41, 1396 (1919).

acetaldehyde are oxidized quantitatively at any given temperature to acetic acid only may be easily calculated.

In view of the above facts, we thought it to be of considerable importance to ascertain the quantitative relationship which might exist between the concentration of the alkali used and the production of vinyl alcohol molecules in an aqueous solution of acetaldehyde.

### Experimental Part.

**Preparation of Acetaldehyde Solution.**—Acetaldehyde was prepared by a modification of the McLeod method<sup>5</sup>. The depolymerized paraldehyde was distilled into a series of small flasks through a 3-bulb Norton and Ott tube, the top bulb of which contained glass beads. The first flask, containing dil. sulfuric acid, was maintained above 40°; the second, between 27° and 40°; the third, between 22° and 27°; the fourth, containing anhydrous cupric sulfate and a calcium chloride tube, below 22°. The cupric sulfate remained almost unchanged in color. The acetaldehyde thus obtained was again distilled below 27° into a weighed amount of water until a sufficient quantity was obtained to make a 2-*M* solution.

**Apparatus and Manipulation.**—The experiment was carried out at 25°. The amount of standardized potassium hydroxide solution chosen

Fig. 1.

for a given experiment was diluted to 145 cc. To the potassium hydroxide solution was added 5 cc. of the acetaldehyde solution (2 *M*) and also 50 cc. of a mercuric chloride solution containing 0.3 g. more of the corrosive sublimate than was necessary to react with the alkali present. The reaction mixture was contained in a 250cc. round-bottom flask and was stirred for 30 minutes. Upon the addition of the mercuric chloride solution the yellow oxide of mercury which formed at first reacted immediately to give a white precipitate with the vinyl alcohol molecules present. This was quickly filtered through an alundum crucible, washed with water, alcohol and ether, then dried over phosphorus pentoxide for 24 hours in a vacuum desiccator. In some experiments the physical

character of the precipitate caused much difficulty in filtration. When the white precipitate was unwashed it changed rapidly into a dark gray

color, this decomposition being accompanied by an evolution of acetaldehyde. After a period of 6 to 8 months, these dark precipitates contained many globules of bright, clean, metallic mercury.<sup>9</sup> However, after being treated as above, the white precipitate remained practically unchanged over a long period of time. The white precipitate obtained in our experiments has remained unchanged in color after two years.

**Character of the Precipitate.**—The white precipitate obtained in these experiments was found to be identical with that obtained by Polleck and Thummel<sup>10</sup> when they attempted to separate mercuric chloride by means of ethyl ether from basic mercuric chloride in potassium or sodium hydrogen carbonate solution. These investigators gave the following formula to their compound,  $\text{CH}_2=\text{CHOHgOHgHgCl}_2$ , and called it vinyl mercury oxychloride. Our analyses showed 82.62% of mercury,<sup>9</sup> (calc. 82.34%).

Nef and Denis<sup>3,4</sup> obtained basic mercury vinylate,  $(\text{CH}_2=\text{CHO})_2\text{Hg}(\text{HgO})$  by a different procedure than that employed in these experiments.

**Results.**—The amounts of vinyl mercury oxychloride formed at the various concentrations of potassium hydroxide used in these experiments are shown in the following table.

KOH per 200 cc. G.	VINYL MERCURY OXYCHLORIDE FORMED.		Acetaldehyde equivalent $\times 10^2$ .
	Molar concentrations of KOH $\times 10^2$ .	$\text{CH}_2=\text{CHOHgOHgHgCl}_2$ . G.	
0.11	0.9804	0.000	0.000
0.20	1.7825	0.003	0.01806
0.28	2.4965	0.36	2.167
0.36	3.2085	0.51	3.071
0.45	4.0107	0.66	3.974
0.62	5.5259	1.10	6.623
0.70	6.2390	1.50	9.031
0.87	7.7540	1.91	11.500
1.20	10.6950	2.72	16.380

From the results of these experiments it is found that the vinyl alcohol production is primarily a function of the concentration of the potassium hydroxide used. Hence it would be expected that the yield of oxalic acid in the oxidation of ethyl alcohol and acetaldehyde by means of potassium permanganate and potassium hydroxide<sup>1,2</sup> would be proportional to the concentration of the alkali used. These results show that a concentration of about 1.40 g. of potassium hydroxide per liter is necessary before an appreciable amount of the white precipitate is obtained. From the experiments of Adkins and one of us<sup>8</sup> it was calculated that a concentration of 1.95 g. of potassium hydroxide per liter is the largest one that may be

<sup>9</sup> Compare *Ber.*, 22, 2867 (1889).

<sup>10</sup> Polleck and Thummel, *ibid.*, 22, 2863 (1889).

employed at 25° without oxalic acid being formed. Hence it is seen that considering the difficulty of handling the white compound of mercury there is a satisfactory concordance in the results of these different experiments.<sup>11</sup> \*

### Summary.

1. Vinyl mercury oxychloride is obtained when alkaline solutions of acetaldehyde are treated with mercuric chloride.

2. The yield of vinyl mercury oxychloride is proportional to the concentration of the alkali present, showing that the production of vinyl alcohol is likewise proportional to the concentration of the alkali.

3. Since the formation of vinyl alcohol is necessary to account for the presence of oxalic acid in the oxidation of ethyl alcohol and acetaldehyde, it follows from (2) that the yield of oxalic acid is also proportional to the concentration of the alkali used.

4. A concentration of about 1.40 g. of potassium hydroxide is necessary for the formation of vinyl at alcohol 25°. This result is in accord with those obtained on the oxidation of acetaldehyde.

## ADDITION REACTIONS OF PHOSPHORUS HALIDES. IV. THE ACTION OF THE TRICHLORIDE ON SATURATED ALDEHYDES AND KETONES.

By J. B. CONANT, A. D. MACDONALD AND A. MCB. KINNEY.

Received May 28, 1921.

### Introduction.

The first paper of this series dealt with the action of phosphorus trichloride on benzaldehyde. The primary addition product formed by these two substances could be decomposed by the action of water or glacial acetic acid with the formation of an  $\alpha$ -hydroxyphosphonic acid. By the use of glacial acetic acid as a medium very good yields of this substance were obtained.<sup>1</sup> The results presented in this paper show that the reaction can be similarly employed for the preparation of hydroxyphosphonic acids from other aldehydes and ketones. The reaction as applied to ketones, however, is of somewhat limited scope. With certain ketones the yields are rather low (about 50%). Aromatic ketones such as benzophenone and benzil, either react only under very much modified conditions, or not at all. Camphor, also, has been found to be very unreactive.

<sup>11</sup> Compare THIS JOURNAL, 41, 1282 (1919); *Am. Chem. J.*, 37, 28 (1907).

<sup>1</sup> THIS JOURNAL, 42, 2337 (1920).

### The Limits of the Reaction.

The initial reaction between the carbonyl group and the trichloride is reversible. In the case of benzaldehyde,<sup>1</sup> the equilibrium point is such that only about 30% of the material is in combination.

The addition product is more reactive than phosphorus trichloride towards acetic acid or acetic anhydride. Therefore, with these reagents it is possible to cause the reaction to run to completion and, in the case of benzaldehyde, to obtain excellent yields with equimolecular amounts of materials. When the temperature is kept below 30° to 35° the acetic acid reacts so rapidly with the addition product that there is no appreciable reaction with the trichloride.

These equations show the probable course of this reaction; a mixture of both the phosphonic (I) and phosphonic (II) acids (or perhaps their acid chlorides) is actually produced. To obtain the hydroxyphosphonic acid (II), the reaction mixture is always poured into water and heated; this completes the conversion of the phosphonic acid into the hydroxyphosphonic acid, (Reaction B).

In the case of benzophenone, anthraquinone, benzil and camphor no phosphonic acid can be obtained by such a procedure. Obviously, it is not expedient to attempt to accelerate the reaction by raising the temperature; acetic acid and phosphorus trichloride react so rapidly above 30° that no satisfactory results can be obtained even with benzaldehyde. Acetic anhydride is less active and, in certain cases which will be considered in a later paper, it has been possible to obtain results by using this reagent at a temperature of 30° to 35°. It was of no service, however, with the ketones just mentioned.

The failure of the reaction with benzophenone can be attributed to one of three possible causes. (1) The equilibrium of the initial reaction is very

far to the left; (2) the addition product is relatively unreactive with the reagents employed; (3) the rate at which the equilibrium of the initial reaction is attained is very slow. The fact that the materials were recovered quantitatively argues against the second possibility—apparently the initial addition reaction had proceeded to only a very slight extent. An increase in temperature would be expected to accelerate the reaction greatly. By thus making the equilibrium more mobile, it should be possible to approach the conditions which are realized at 25° with simple aldehydes and ketones. The effect of temperature on the equilibrium point cannot be predicted, but the position of the equilibrium is of not much importance *provided the rate of the reaction is relatively great*. In order to parallel the usual procedure at a higher temperature, it is necessary to find some substance to replace the acetic acid. This substance must react only slowly with the trichloride at the given temperature, but rapidly with the addition product. The similarity between the addition product and the pentachloride enabled us to investigate this point by studying the behavior of several reagents towards the pentachloride. A number of experiments with various compounds led us to believe that benzoic acid would be suitable. A trial with this reagent and benzaldehyde at a temperature of 145° to 150° was successful. Benzoyl chloride and the phosphonic acid were formed. The method was then applied to benzophenone with satisfactory results. At a temperature of 155° the reaction seemed to run with benzoic acid much as it did with simple ketones and acetic acid at room temperature; a 50% yield of the desired hydroxyphosphonic acid was obtained. With camphor there was also apparently a reaction, although the product was not isolated in a pure state. Anthraquinone and benzil could not be made to react even by this procedure, and it has not been possible, as yet, to cause them to combine with phosphorus trichloride.

### Isolation of the Product.

The isolation of the hydroxyphosphonic acid is a difficult problem in many cases. Many of the substances crystallize with difficulty and are very soluble in water. Evaporation of the aqueous solution in some instances yields a gum which slowly solidifies. After drying on a porous plate it can be recrystallized. In some cases no crystalline acid could be obtained and the product was isolated as the lead salt.

The reaction with acetophenone and acetone is complicated by the fact that an unsaturated phosphonic acid is also formed to some extent. This was first noticed because the aqueous solution of the product rapidly decolorizes bromine water. In this work the weight of the crude mixture of saturated and unsaturated acids was determined and the yield calculated from this. A subsequent paper will discuss the mechanism of the

formation of these acids which have the formula  $RC(PO_3H_2)=CH_2$ . The unsaturated acid was obtained pure in the case of acetophenone. Its structure follows from its oxidation to formaldehyde by chromic acid.

The results of this research indicate the limits of the reaction of the trichloride with unsubstituted aldehydes and ketones. The results are summarized in the following table. An excess of trichloride was used in every case. As this varied with the experiment and the conditions of isolating the material are obviously inaccurate, the variations in the yields are of no great significance.

Carbonyl compound.	Medium.	Yield of phosphonic acid. %	How isolated.
$C_6H_5COCH_3$	$CH_3COOH$	96	crude mixture, partially unsaturated.
$CH_3COCH_3$	$CH_3COOH$	91	crude mixture, partially unsaturated.
$CH_3COCH_2CH_3$	$CH_3COOH$	76	as lead salt.
$C_2H_5COC_2H_5$	$CH_3COOH$	67	as lead salt.
$(CH_3)_3CCOCH_3$	$(CH_3CO)_2O$	56	as lead salt.
$CH_3(CH_2)_5CHO$	$CH_3COOH$	76	as lead salt.
$(C_6H_5CH_2)_2CO$	$CH_3COOH$	44	crude crystals.
$C_6H_5CH_2CH_2COC_6H_5$	$CH_3COOH$	48	recrystallized acid.
$(C_6H_5CH_2CH_2)_2CO$	$(CH_3CO)_2O$	56	recrystallized acid.
$C_6H_5COC_6H_5$	$C_6H_5COOH$ (150°)	50	recrystallized acid.
Camphor	$C_6H_5COOH$ (150°)		not isolated.
$C_6H_5COCOC_6H_5$			no reaction under any conditions.
Anthraquinone			no reaction under any conditions.

### Experimental.

#### General Procedure with Acetic Acid.

The general procedure which was employed when acetic acid was used as a medium is essentially as follows. The phosphorus trichloride was added to the carbonyl compound, while the temperature was kept below 35°; this requires considerable cooling in some cases. An excess of the trichloride was employed; this was usually only about 10%, but in certain cases was much more. The mixture was protected from moisture and allowed to stand for from 2 to 3 hours. A slight excess (three times the molecular amount) of glacial acetic acid was then added, while the temperature was kept between 20° and 30°. After the reaction mixture had stood 12 hours longer, it was poured into 300 cc. of ice-water and shaken vigorously. The aqueous solution was now evaporated to dryness on the steam-bath. The gum which formed was allowed to crystallize. In some cases this was a very slow process and took from one day to two weeks. The crystalline mass could then be dried on a clay plate and finally in a vacuum desiccator over sodium hydroxide.

In those cases in which no crystallization took place, the lead salt was prepared. The gum was dissolved in about 200 cc. of water, made strongly alkaline with ammonia and then treated with magnesium nitrate. After

it had stood overnight, the precipitated magnesium ammonium phosphate was filtered off. The solution was then diluted to 500 cc., made just acid with acetic acid, and heated to boiling. A solution of lead acetate or nitrate was added in excess, the mixture was boiled for 5 or 10 minutes to coagulate the lead salt and the solution was filtered. The lead salt was washed with boiling water and then dried. Prepared in this way, the lead salt was free from phosphate and practically free from chloride. Experiments had shown that the phosphorous acid, first formed by the excess of the trichloride and the water, would be completely oxidized to phosphoric acid during the evaporation. Thus, there was no necessity of removing this acid from the mixture. Most of the hydrochloric acid also is removed during the evaporation; the amount that is left does not interfere, since lead chloride is soluble in boiling solution whereas the lead salts of the phosphonic acids are practically insoluble.

**Acetophenone.**—Ten g. of acetophenone and 15 g. of trichloride (25% excess) yielded 16 g. of crude acid after it had been dried for 15 hours. The crude material contained about 63% of the unsaturated acid. The theoretical yield of the hydroxy acid would be 16.7 g. Percentage yield, about 96%. The pure unsaturated acid may be obtained by crystallization from a mixture of benzene and carbon tetrachloride.

**$\alpha$ -Phenyl-vinyl-phosphonic Acid,  $C_6H_5C(PO_3H_2)=CH_2$ .**—The acid, thus prepared, is very soluble in water, fairly soluble in alcohol and only slightly soluble in benzene. It melts at  $112^\circ$ .

**Analyses.** Calc. for  $C_8H_9O_3P$ : P, 16.9; C, 52.2; H, 4.9. Found: P, 16.6; C, 52.2; H, 5.2.

The acid was shown to be dibasic by titration with standard alkali. The aniline salt was made by the action of aniline on an alcohol-ether solution of the acid. It was recrystallized from alcohol and melted at  $180^\circ$  to  $181^\circ$ . It was soluble in water and insoluble in ether.

**Analysis.** Calc. for  $C_{14}H_{16}O_3NP$ : N, 5.15. Found: 5.09.

The phenyl-vinyl-phosphonic acid decolorizes bromine water immediately and bleaches permanganate solution. Its structure follows from these reactions, its analysis and the formation of formaldehyde on oxidation with chromic acid. 0.1 g. of substance was oxidized with 0.2 g. of chromic acid and the evolved gases passed into water. The water gave the characteristic resorcin test for formaldehyde.

**Acetone.**—Ten g. of acetone and 30 g. of trichloride (12% excess) yielded a crystalline mass which, when dry, weighed 17 g. A sample titrated with bromine water showed that it contained about 30% of an unsaturated acid. By recrystallization from hot glacial acetic acid, the  $\alpha$ -hydroxy-*isopropyl*-phosphonic acid was obtained, m. p.  $167^\circ$  to  $169^\circ$ . The same acid has been prepared by Marie<sup>2</sup> by adding phosphorous acid to acetone and oxidizing the product. The percentage yield, based on the weight of the crude material was 91%.

**Methylethyl Ketone.**—Ten g. of methylethyl ketone and 25 g. of trichloride (30% excess) yielded 38 g. of the lead salt, or 76% calculated amount. No crystalline acid could be obtained.

**Lead Salt of  $\alpha$ -hydroxy- $\alpha$ -methyl-propyl-phosphonic Acid,  $C_2H_5C(PO_3Pb)OHCH_3$ .**—The salt is insoluble in hot and cold water, but soluble in fairly strong nitric acid. It

<sup>2</sup> Marie, *Compt. rend.*, 133, 221 (1901).

was free from phosphates and chlorides. A sample of it, when tested with bromine water, showed that it contained only a trace of unsaturated acid.

*Analysis.* Calc. for  $C_4H_9O_4PPb$ : Pb, 55.7. Found: 55.5.

**Ethylpropyl Ketone.**—Ten g. of ethylpropyl ketone and 15 g. of trichloride (7% excess) yielded 25.8 g. of lead salt, (67%). No crystalline acid could be obtained; a thick oil only partially soluble in water but soluble in alkalis could be isolated but not purified.

**Lead Salt of  $\alpha$ -Hydroxy- $\alpha$ -ethyl-butyl-phosphonic Acid,  $C_4H_7C(PO_3Pb)OHC_2H_5$ .**—The salt was free from chlorides and contained only a trace of unsaturated acid.

*Analysis.* Calc. for  $C_6H_{13}PO_4Pb$ : Pb, 53.5. Found: 54.4.

**Pinacolone.**—Acetic anhydride was substituted for the acetic acid in the experiments with this compound. The resulting phosphonic acid is very unstable and there seemed to be less decomposition with acetic anhydride as a medium than with acetic acid. During the mixing of the ketone and the trichloride the temperature must be kept below 25°. After the addition of the anhydride the temperature was kept at 30° to 35° for several hours, then the mixture was poured into water. A dark oil separated from the aqueous solution. The acid was unstable, particularly when warmed, and could not be obtained crystalline. A lead salt was prepared by the usual procedure. 10 g. of pinacolone and 15 g. of trichloride (17% excess) gave 22.6 g. of lead salt, a 56% yield.

**Lead Salt of  $\alpha$ -hydroxy- $\alpha$ -methyl- $\beta$ -dimethyl-propyl-phosphonic Acid,  $(CH_3)_3C-C(PO_3Pb)(OH)(CH_3)$ .** The salt was very hygroscopic. After drying it for a month in a vacuum desiccator over sulfuric acid it gave the following analysis.

Calc. for  $C_6H_{13}O_4PPb$ : Pb, 52.6. Found: 51.4, 51.4.

The low values may be due to water still in combination with the compound. The salt was free from phosphate, chloride and unsaturated compounds.

**Heptyl Aldehyde.**—Ten g. of *n*-heptyl aldehyde and 16 g. (25% excess) of trichloride gave 12 g. of a lead salt or a yield of 76%. The gum obtained by evaporation of the aqueous solution of the reaction mixture slowly solidified; it was converted into the lead salt in order to determine the yield. When the lead salt was decomposed with hydrogen sulfide and the aqueous solution evaporated, the crystalline acid could be obtained.

In another experiment in which a somewhat purer sample of aldehyde was used in slight excess, 11 g. of solid phosphonic acid was obtained (76%) yield. Recrystallization from water yielded the pure hydroxyphosphonic acid melting at 165° to 173°. The compound is identical in its properties with the hydroxyphosphonic acid made by Fossick from an excess of trichloride and heptylaldehyde.<sup>3</sup>

**Dibenzyl Ketone.**—Five g. of the ketone and 6 g. of the trichloride (90% excess) yielded a crystalline mass which weighed 3 g. when dry. A test showed that no unsaturated acid was present.

**$\alpha$ -Benzyl- $\alpha$ -hydroxy- $\beta$ -phenyl-ethyl-phosphonic Acid,  $C_6H_5CH_2(PO_3H_2)OHCH_2C_6H_5$ .**—The acid can be recrystallized from benzene. It melts at 181° to 182°.

*Analysis.* Calc. for  $C_{18}H_{17}O_4P$ : C, 61.4; H, 5.8; P, 10.6. Found: C, 61.3; H, 5.9; P, 10.6.

**Benzyl-acetophenone.**—Three g. of the ketone and 3 g. of trichloride (20% excess) yielded 5 g. of sticky crystals. These were dissolved in glacial acetic acid, and water was added very slowly to the solution kept at -10°. The crystals which formed could be recrystallized from benzene. Two g. of purified acid was obtained, a 48% yield.

**$\alpha$ -Phenyl- $\alpha$ -hydroxy- $\gamma$ -phenol-propyl-phosphonic Acid,  $C_6H_5C(PO_3H_2)OHCH_2CH_2$**

<sup>3</sup> Fossick, *Monatsh.*, 7, 27 (1886).

$C_6H_5$ .—The acid melts at  $165^\circ$  to  $168^\circ$ ; it is practically insoluble in water, but is soluble in alcohol, ether and acetic acid. It did not decolorize bromine water.

*Analysis.* Calc. for  $C_{15}H_{16}PO_4$ : P, 10.6. Found: 10.8.

**Dibenzyl-acetone.**—Two g. of the ketone and 2 g. of the trichloride (80% excess) yielded 5 g. of very impure crystals which, however, contained no unsaturated acid. Recrystallization from benzene yielded 1.5 g. of pure solid (56%). Acetic anhydride was used as the medium in this experiment.

**$\alpha$ -hydroxy- $\alpha$ -( $\beta$ -phenyl ethyl)- $\gamma$ -phenyl-propyl-phosphonic Acid,  $(C_6H_5CH_2CH_2)_2C(OH)(PO_3H_2)$ .**—This substance melts at  $173^\circ$  to  $174^\circ$ . It is insoluble in water but completely soluble in a solution of sodium hydrogen carbonate.

*Analysis.* Calc. for  $C_{17}H_{21}O_4P$ : P, 9.7. Found: 10.6.

### Procedure with Benzoic Acid at a High Temperature.

As stated in the introduction, benzil, camphor, benzophenone and anthraquinone were recovered completely unchanged by all procedures involving acetic acid or anhydride. Not a trace of a phosphonic acid could be detected. The high temperature procedure in which benzoic acid is used was first tried with benzaldehyde as described in the following experiment.

Ten g. of benzaldehyde and 40 g. of benzoic acid were mixed in a flask equipped with a reflux condenser, and heated on the steam-bath. Sixteen g. of phosphorus trichloride (1.3 mols) was added and the reaction mixture heated to  $150^\circ$ . After 45 minutes the molten mass was poured into 300 cc. of water and the mixture was heated on the steam-bath until all the material had dissolved. The solution was then cooled in ice and the benzoic acid filtered off. The filtrate was evaporated to dryness, the residue dissolved in 10 cc. of water and a small amount of benzoic acid filtered off. The filtrate was evaporated to dryness and the phosphonic acid converted into the aniline salt by treatment with aniline in an alcohol-ether solution. Several crystallizations of the aniline salt from alcohol yielded 7.4 g. of material melting at  $201^\circ$ . It was identical with the aniline salt previously described.<sup>1</sup> The yield of purified material was 26% of that calculated.

**Benzophenone.**—Ten g. of benzophenone and 20 g. of benzoic acid were mixed and heated on the steam-bath until molten. Ten g. of phosphorus trichloride (55% of excess) was added in small portions during a period of 5 to 10 minutes. The temperature was gradually raised in the course of 10 minutes to  $155^\circ$ , and then allowed to fall to  $130^\circ$  and kept constant at this point for 2 to 3 hours. The melt was cooled to  $90^\circ$  and poured into 500 cc. of water. The mixture was made strongly alkaline with sodium hydroxide and heated on the steam-bath for from 4 to 5 hours. During this treatment, the oil which separated when the melt was first poured into water, decreased appreciably. The solution was diluted to 750 cc., cooled and the unchanged benzophenone removed by extracting it with ether. To separate the benzoic acid, the solution was acidified strongly with hydrochloric acid, then cooled and filtered. The filtrate was evaporated to a volume of 250 cc. and extracted thrice with ether. The ethereal solution on evaporating yielded an oil which finally solidified. Fractional crystallization from slightly acidulated water gave 7 g. of a phosphonic acid melting at  $171^\circ$  to  $172^\circ$ , and 2.5 g. of another acid containing phosphorus whose constitution was not established. Perhaps it was formed by the replacement of a hydrogen atom of the nucleus by the radical  $-PCl_2$ .

**$\alpha$ -Hydroxy-diphenyl-methyl-phosphonic Acid**,  $(C_6H_5)_2C(OH)(PO_3H_2)$ .—The acid melts at  $171^\circ$  to  $172^\circ$ . It is readily soluble in alcohol, in ether and in hot water and somewhat soluble in cold water.

*Analysis.* Calc. for  $C_{13}H_{13}O_4P$ : P, 11.7. Found: 11.7.

The constitution of the acid is established by the fact that it is oxidized by permanganate with the formation of benzophenone and phosphonic acid. Two g. of the acid dissolved in 10 cc. of sodium carbonate solution was treated with potassium permanganate until a permanent pink color resulted. The dioxide and a yellow solid separated and were filtered off. The filtrate gave a strong test for the phosphate ion. The yellow solid on recrystallization gave 0.5 g. of benzophenone which was identified by the method of mixed melting points.

**Camphor.**—The procedure just outlined for benzophenone was applied to camphor. A few grams of an oil was obtained, evidently an acid material, slightly soluble in water and containing phosphorus. No large amount of crystalline material could be secured, so the compound was not investigated further.

Anthraquinone and benzil showed no evidence of reaction when treated by the high temperature-benzoic acid procedure. The materials were recovered unchanged and no trace of a phosphonic acid could be detected.

### Summary.

1. The limits of the action of phosphorus trichloride on saturated aldehydes and ketones has been studied. By the use of glacial acetic acid or acetic anhydride as a medium, hydroxyphosphonic acid can be obtained from most ketones.

2. The products were isolated either as crystalline acids or as lead salts.

3. With acetophenone and acetone, an unsaturated phosphonic acid is also produced. This has been isolated in one instance and its constitution established.

4. Benzophenone will not combine with phosphorus trichloride by the usual procedure. At  $150^\circ$ , with benzoic acid in place of acetic acid satisfactory results can be obtained.

5. It has not been possible by any procedure to add the trichloride to benzil or anthraquinone.

[CONTRIBUTION FROM THE UNIVERSITY OF MANCHESTER.]

THE PREPARATION OF PYRIDINE AND OF CERTAIN OF ITS  
HOMOLOGS IN A STATE OF PURITY.

BY JOSEPH GREENWOOD HEAP, WILLIAM JACOB JONES AND JOHN BAMBER SPEAKMAN.

Received June 8, 1921.

The preparation of highly purified pyridine has not yet been described, while in the case of its homologs widely discordant results are recorded for the physical properties. It was therefore considered of interest to undertake the preparation of the bases in a pure form.

## Pyridine.

Crude coal tar bases vary greatly both in the nature and in the proportion of the bases which they contain. The nature of the bases depends on whether they are derived from light or middle oil. The following results were obtained with bases derived from a light oil.

The crude bases were dehydrated with solid sodium hydroxide. From 2 liters 800 cc. of a pyridine fraction, b. p.  $113^{\circ}$  to  $117^{\circ}$ , and 200 cc. of a 2-methylpyridine fraction, b. p.  $127^{\circ}$  to  $130^{\circ}$ , were obtained after six successive fractional distillations through a glass fractionating column 110 cm. long and 2 cm. in diameter (Col. A).

Pure pyridine was obtained by converting the former fraction into the pure compound  $2C_5H_5N \cdot ZnCl_2$ . For this purpose, 845 g. of zinc chloride is dissolved in a mixture of 690 cc. of water, 345 cc. of conc. hydrochloric acid (sp. gr. 1.18) and 690 cc. of absolute alcohol. One liter of the pyridine fraction is added to this mixture.

A crystalline precipitate is obtained which is separated from the mother liquor and recrystallized twice from absolute alcohol. To liberate the base, a concentrated aqueous solution of 26.7 g. of sodium hydroxide is added to 100 g. of the dry recrystallized compound. The base with dissolved water is separated from the precipitate by filtration and is dried over solid sodium hydroxide. This sample of pyridine, on distillation in a dry apparatus, distills completely at  $115.3^{\circ}$ , measured on the international hydrogen scale, under 760 mm. of mercury. The mass of 1 cc. of pyridine at  $25^{\circ}$  ( $d_4^{25}$ ) is 0.9776 g. All weighings were corrected for air displacement. Previous determinations of the boiling point are as follows.

Innes,<sup>1</sup>  $115.2^{\circ}$  to  $115.5^{\circ}$ ; Constam and White,<sup>2</sup>  $115.2^{\circ}$ ; Zawidzki,<sup>3</sup>  $115.1^{\circ}$  to  $115.3^{\circ}$ ; Hartley, Thomas and Applebey,<sup>4</sup>  $115.3^{\circ}$  to  $115.4^{\circ}$ . The density ( $d_4^{25}$ ) is variously given as 0.97721 (Hartley, Thomas and Applebey), 0.97795 (Zawidzki), 0.97832 (Dunstan, Thole and Hunt).<sup>5</sup>

## 2-Methylpyridine.

2-methylpyridine can be prepared by a method analogous to the method for 3-methylpyridine, if the fraction distilled from crude bases between 127° and 130° is used. The resulting product, in a dry apparatus, distils completely at 127.8° to 9°, measured on the international hydrogen scale, under 760 mm. of mercury. The mass of 1 cc. at 25° ( $d_{4}^{25}$ ) is 0.9404 g. when all weighings are corrected for air displacement.

Thorpe<sup>6</sup> gives b. p. 133.5°;  $d_{4}^{25}$  0.9384,  $d_{4}^{20}$  0.9616; Ladenburg and Lange<sup>7</sup> give b. p. 129°,  $d_{4}^{20}$  0.9652; Constam and White<sup>2</sup> give b. p. 128.8,  $d_{4}^{15}$  0.9497; Garrett and Smythe<sup>8</sup> give b. p. 129.4°.

## 3-Methylpyridine.

(A) Two liters of crude bases derived from a light oil was dehydrated with solid sodium hydroxide and the dry oil was fractionally distilled twelve times successively through a Young's<sup>9</sup> 8-chamber evaporator fractionating column, 110 cm. long and 3 cm. in diameter. Fractions were collected at every degree from 120° to 150°. The fraction 143° to 144° (227 cc.) was converted into the zinc chloride compound,  $2C_6H_7N \cdot ZnCl_2$ , by dissolving it in 1135 cc. of water and adding the solution to a conc. aqueous solution of 243 g. of zinc chloride clarified by treatment with hydrochloric acid. The precipitate was separated from the mother liquor, dried, and weighed. The 360 g. obtained was dissolved in 1400 cc. of boiling absolute alcohol. When the solution was cooled to room temperature, the zinc chloride compound crystallized. It was recrystallized from alcohol, until its melting point, determined in a sealed tube, was unaltered by further crystallization. Four crystallizations sufficed, and the melting point was 115°. The 93 g. of the zinc chloride compound of 3-methylpyridine obtained, was decomposed by treatment with a concentrated aqueous solution of 24 g. of sodium hydroxide. The base containing dissolved water, separated by filtration, was dried over solid sodium hydroxide. When placed in a dry apparatus, it distilled completely at 143.8°, measured on the international hydrogen scale, under 760 mm. pressure. The mass of 1 cc. at 25° is 0.9515 g. All weighings were corrected for air displacement.

Previous determinations of the boiling point are as follows: Schwarz,<sup>10</sup> 143.5°; Constam and White,<sup>2</sup> 143.4°; Flaschner,<sup>11</sup> 143.9°; Constam and White give  $d_{4}^{15}$  0.96134 for 3-methylpyridine.

The base obtained in this manner was found to be completely miscible with water between 15° and 100°. It was identified as 3-methylpyridine by oxidation to the

<sup>6</sup> Thorpe, *J. Chem. Soc.*, 37, 222 (1880).

<sup>10</sup> Schwartz, *Ber.*, 24, 1676 (1891).

<sup>11</sup> Flaschner, *J. Chem. Soc.*, 95, 668 (1909).

carboxylic acid, pyridine-3-carboxylic acid, which without further purification melted sharply at  $228^{\circ}$  in a sealed tube. Since the acid gave no red coloration with ferrous sulfate solution, complete absence of any 2-6 dimethylpyridine in the sample of 3-methylpyridine may be assumed.

The oxidation was carried out in the following manner. Four g. of the base was dissolved in 400 cc. of water and 13.6 g. of potassium permanganate added. The mixture was heated on the steam-bath and a continuous stream of carbon dioxide ~~was~~ passed through it during the period of oxidation. The passage of carbon dioxide improves the yield of the carboxylic acid, presumably because the free potassium hydroxide formed during oxidation in the absence of carbon dioxide, decomposes the acid with formation of pyridine.

After 6 hours, the hot liquid was filtered. The precipitate of manganese dioxide was boiled with water and the solution filtered. The combined filtrates were concentrated to small volume, neutralized with sulfuric acid, cooled and treated with silver nitrate. The solid silver salt of pyridine-3-carboxylic acid was collected on a filter and washed with distilled water; then it was suspended in distilled water and a stream of hydrogen sulfide was passed through the liquid. After the liquid had been boiled, the precipitate of silver sulfide was removed and the filtrate was evaporated to dryness. A white residue of the carboxylic acid was obtained; m. p.  $228^{\circ}$ .

(B) 3-Methylpyridine can also be obtained from crude pyridine bases of middle oil. The crude bases were dried over solid sodium hydroxide and 3 liters of the dry oil was 5 times successively fractionally distilled through Column A; fractions were collected every degree from  $139^{\circ}$  to  $170^{\circ}$ . The fractions from  $139^{\circ}$  to  $143^{\circ}$ , total volume 200 cc., were combined and converted into the zinc chloride compound by the method described under (A). An oil separated which would not crystallize even on standing for 24 hours. This oil was collected, dissolved in 800 cc. of boiling alcohol and concentrated to half the volume. Crystallization could be brought about only by cooling the solution to  $-15^{\circ}$ . (The further treatment of the mother liquor is described under the preparation of 2,6-dimethylpyridine.) The crystals were redissolved in 250 cc. of boiling alcohol and the solution was cooled again to  $-15^{\circ}$ . The crystals which then separated were dissolved once more in 250 cc. of boiling alcohol. When this solution cooled to room temperature, crystallization occurred. Two recrystallizations from 250 cc. of alcohol sufficed to give a product, m. p.  $115^{\circ}$ , whose melting point was unaltered on recrystallization.

The base obtained from these crystals was identical in all respects with the 3-methylpyridine described under (A).

We find that 3-methylpyridine is completely miscible in all proportions with water between 15 and  $100^{\circ}$ ; therefore our results conflict with those of Flaschner<sup>11</sup> who states that 3-methylpyridine is only partially miscible with water. There is no doubt that Flaschner was dealing with a mixture containing 2,6-dimethylpyridine, which we find to be partially miscible with water, and that he did not obtain pure 3-methylpyridine. In contrast to our procedure, Flaschner did not identify any of the materials/

he dealt with. Therefore we can state positively that his re 3-methylpyridine are incorrect.

It is difficult to see how Flaschner could have obtained 4-pyridine by crystallization of the zinc chloride compound, since C and White<sup>2</sup> state that 4-methylpyridine is a very weak base. Bo-stam and White, and Meisenheimer<sup>12</sup> had to resort to crystallization mercuric chloride compound for the preparation of this base. In ad we have failed entirely to repeat Flaschner's preparation of 4-methylpyridine, the product which we obtained proving to be 3-methylpyridine.

### 2,6-Dimethylpyridine.

When the alcoholic mother liquor from the first crystallization of zinc chloride compound of 3-methylpyridine (Section B under "3-methylpyridine") stood for several days, it separated into two layers. The sirupy layer contained the whole of the zinc chloride compound and separated (224 g.). Fifty g. of sodium hydroxide was added in the of a concentrated aqueous solution and the regenerated base dried sodium hydroxide. The 107 cc. of base obtained was mixed with 10% of conc. hydrochloric acid (sp. gr. 1.18) and then added to a solution 542 g. of mercuric chloride dissolved in 2 liters of boiling alcohol. The compound,  $C_7H_9N.HCl.2HgCl_2$ , which separated when the solution was cooled to 15° was recrystallized five times from 1400 cc. of boiling alcohol. The product obtained melted at 131° in a sealed tube, and its melting point was unaltered by further crystallization. Yield, 147 g. This was decomposed with a concentrated aqueous solution of 50 g. of sodium hydroxide. The base containing dissolved water separated by filtration from the precipitated mercuric oxide was dried over solid sodium hydroxide and distilled in a dry apparatus. Thus only 13 g. of pure base was obtained and in consequence an accurate reading of the boiling point was not possible; that observed was about 137.5°. The mass of 1 cc. of 2,6-dimethylpyridine at 25° is 0.9200 g. The base was not completely miscible with water at 90°. It was identified as 2,6-dimethylpyridine by oxidation to pyridine-2,6-dicarboxylic acid, which melted sharply at 228° in a sealed tube. In an open tube the acid melted with decomposition. An aqueous solution of the acid, on addition of ferrous sulfate solution, gave a red color, followed by precipitation of a grayish precipitate, presumably an iron salt of the acid. The red coloration indicates the presence of a methyl group in Position 2 in the original base.

### 2,4-Dimethylpyridine.

The material used for the preparation of this base was the fractions distilled between 155° and 156°, and between 156° and 157°, obtained in the

<sup>12</sup> Meisenheimer, *Ann.*, 420, 197 (1920).

ation described under "3-Methylpyridine," Section B. The total 200 cc., was converted into the compound  $C_7H_9N.HCl.2HgCl_2$  by adding it with 187 cc. of conc. hydrochloric acid and adding the mixture to a solution of 950 g. of mercuric chloride in 3600 cc. of boiling absolute alcohol. The compound which separated as the solution cooled to  $15^\circ$  was crystallized four times from 1 liter of boiling alcohol. The melting point of the product was  $128^\circ$ , which remained unaltered by further recrystallization. The yield was 80 g.

The base was regenerated by treatment with a concentrated solution of 19 g. of sodium hydroxide. The base containing dissolved water was separated from the precipitate by filtration and was dried over solid calcium hydroxide. Through a dry apparatus the base distilled completely at  $1^\circ$  under 760 mm. pressure. The mass of 1 cc. at  $25^\circ$  is 0.9273 g.

In water it gives a minimum critical solution temperature of  $22.5^\circ$ . The base was identified as 2,4-dimethylpyridine by oxidation to pyridine-2,4-dicarboxylic acid by the method described in the case of 3-methylpyridine, using double the proportion of potassium permanganate. The product melted sharply at  $241^\circ$ ; vigorous evolution of carbon dioxide commenced at once, indicating a dicarboxylic acid. An aqueous solution of the acid gave a deep red coloration with ferrous sulfate solution, which indicates a methyl group in Position 2 in the original base.

### Summary.

Pure samples of pyridine and certain of its homologs have been prepared. Boiling points and densities have been determined and found to be as follows: pyridine, b. p.  $115.3^\circ$ ,  $d_4^{25}$  0.9776; 2-methylpyridine, b. p.  $128-9^\circ$ ,  $d_4^{25}$  0.9404; 3-methylpyridine, b. p.  $143.8^\circ$ ,  $d_4^{25}$  0.9515; 2,6-dimethylpyridine, b. p. about  $137.5^\circ$ ,  $d_4^{25}$  0.9200; 2,4-dimethylpyridine, b. p.  $157.1^\circ$ ,  $d_4^{25}$  0.9273.

MANCHESTER, ENGLAND.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE UNIVERSITY OF MICHIGAN.]

### PHENYL-THIO-XANTHYL.

BY M. GOMBERG AND WESLEY MINNIS.

Received June 8, 1921.

The free radical, phenyl-thio-xanthyl (I), differs structurally from phenyl-xanthyl (II) only in the substitution of a sulfur for an oxygen

atom. The difference in the degree of dissociation of the dimolecular ~~two~~ radicals, as reported in the literature, is therefore

quite perplexing. Schlenk and Renning<sup>1</sup> found 82% of the latter substance to be monomolecular by determining the molecular weight in a boiling benzene solution of 1.5% concentration, while they report only 14% of the former to be monomolecular in freezing benzene (0.7% solution). A later investigation<sup>2</sup> showed phenyl-xanthyl to be 70% monomolecular in freezing naphthalene (1.5% solution).

As Schmidlin<sup>3</sup> justly observes, molecular-weight determinations of free radicals are of value only when accompanied by the determinations of oxygen absorption. Otherwise unnoticed transformations or isomerizations of the radicals may vitiate the results. The results of Gomberg and Schoepfle on phenyl-xanthyl were checked by parallel oxygen absorptions; it now seemed desirable to repeat the investigation of phenyl-thio-xanthyl, controlling the work by this essential test.

Phenyl-thio-xanthenol chloride,  $\text{S} \begin{array}{c} \diagup \text{C}_6\text{H}_4 \\ \diagdown \text{C}_6\text{H}_4 \end{array} \text{C} \begin{array}{c} \diagup \text{C}_6\text{H}_5 \\ \diagdown \text{Cl} \end{array}$  —Phenyl-thio-

xanthenol was prepared from thio-xanthone and phenyl magnesium bromide,<sup>4</sup> the thio-xanthone having been made from thiosalicylic acid.<sup>5</sup> The xanthenol used in this work was recrystallized from hot petroleum ether (100–110°), and had a melting point of 105° or over.

The red additive compound, phenyl-quino-thio-xanthenol chloride-hydrochloride<sup>6</sup> was made by passing a slow stream of dry hydrogen chloride into a concentrated ethereal solution of the carbinol. It is quite insoluble in this solvent. The red crystals were quickly filtered, washed, and dried in a vacuum desiccator over sulfuric acid.

Various procedures were investigated in order to arrive at the most satisfactory method for removing the extra molecule of hydrochloric acid. The simplest procedure proved to be the best. Ten g. of chloride-hydrochloride was suspended in 100 cc. of dry benzene in a distilling flask which carried an extra side arm sealed into the bulb. Through a glass tube inserted in this side arm there bubbled through the liquid a stream of air, dried by passing through conc. sulfuric acid and phosphorus pentoxide. The flask was heated in a glycerine bath to 90°, the solid gradually went into solution and the deep red color lightened considerably. The solvent was completely distilled in the course of 1½ hours, the last portion being removed under reduced pressure to avoid superheating. On cooling, the deep red oil became a mass of lighter colored crystals, from which after recrystallization from a large quantity of dry ether in the absence of moist air, colorless crystals of chloride were obtained. They turned reddish when dried in a stream of air, in spite of most efficient drying systems. Once dry, the crystals could be preserved in a vacuum desiccator for a long time with little change. Yield 60 to 70%.

In this preparation, heating for too long a period gives a deep red gum which will not crystallize, or else crystallizes as an impure product, and in lower yield.

**Oxygen Absorptions.**—The preparation of the free radical is difficult because of the sensitivity of the chloride to traces of water, with which it forms carbinol and hydrochloric acid, retaining the latter as the additive salt. The presence of free acid has been shown repeatedly to be harmful to the existence of a free radical. The instability of this free radical, as indicated by the following data, may be due to the influence of acid, although it is also possible that the radical spontaneously polymerizes because of other influences, *e. g.*, light, heat. The nature of the solvent is clearly an important factor, so far as the speed of the change is concerned.

All measurements were made by sealing chloride, molecular silver, and the solvent in a glass tube, shaking at room temperature for the specified time, and measuring the absorption of oxygen in the usual apparatus.<sup>7</sup>

(*a*) Shaken with solvent and silver in absorption apparatus.

This record of the progressive disappearance of the free radical in solution, as time elapses, makes its instability most apparent and indicates the improbability of isolating it in the solid state.

**Attempts to Isolate the Free Radical.**—Preliminary trials with chloride and silver, shaken in ether, acetone or ethyl acetate, showed the latter two to be undesirable, since the brown-red solutions changed to a straw yellow in 24 hours. The free radical in solution possesses high tinctorial power; no difference in shade or depth of color can be noted between benzene or bromobenzene solutions giving either high or low values for

<sup>7</sup> Gomberg and Schoepfle, *THIS JOURNAL*, 39, 1661 (1917).

oxygen absorption, so that the qualitative test of decolorization with oxygen is misleading unless accompanied by the quantitative measure of absorption.

Using ether as solvent, chloride and silver were shaken one hour. On working up in the usual manner, a dark oil was obtained which changed to light red crystals in the course of a day. These crystals could not be redissolved in a large quantity of ether, showing that the original soluble product was no longer present. Redissolved in benzene and treated with petroleum ether, they formed a light pink precipitate without crystalline structure. This material did not absorb oxygen, did not contain chlorine, and did not melt under 240°.

Since bromobenzene solutions appeared to be relatively stable, these were used with a 30-minute shaking period. To avoid the high temperature otherwise necessary to distil the solvent, distillation was dispensed with altogether. A large amount of petroleum ether was added to the solution precipitating a red-brown amorphous mass, which when washed with ether, became light pink. The test for oxygen absorption was made on the final dry product within 5 hours from the beginning of the experiment, but no oxygen was absorbed.

The procedure of Schlenk and Renning<sup>1</sup> was next duplicated. Copper bronze ("Naturkupfer C," which they also had used) was washed with alcohol and with ether, and dried in a stream of hydrogen at 250° for 3 hours. Its efficiency was demonstrated by preparing triphenylmethyl in boiling benzene solution under exactly the same conditions used later for phenyl-thio-xanthyl. 4.4 g. of pure phenyl-thio-xanthienol chloride and 20 g. of copper bronze were placed in a flask and protected by an atmosphere of carbon dioxide. Sixty cc. of dry thiophene-free benzene was admitted and heated to the boiling temperature in a glycerine bath. A stream of dry carbon dioxide was passed through the apparatus during the whole time of heating. Ten minutes was required to bring the benzene to boiling, heating was continued for 45 minutes and the red-brown solution was filtered into the free radical apparatus, together with 15 cc. of warm benzene. The solvent was evaporated under reduced pressure to  $\frac{1}{3}$  its volume and cooled. Since no precipitate appeared, petroleum ether was added and cooling continued overnight. Only a slight deposit of dark red-brown crystals had formed by the next morning, so a large quantity of petroleum ether was used, which threw down a pink amorphous solid. The mother liquor was removed and the product dried at room temperature in a stream of carbon dioxide. Yield, 3.0 g.

Oxygen absorption: 0.5763 g. of substance in xylene solution absorbed 1.3 cc. (N. T. P.) of oxygen, which is 5.5% of the calculated absorption for pure free radical.

The experiment was repeated with the precipitation of the product with petroleum ether immediately after partial evaporation of the solvent, so

that the oxygen absorption was measured 4 hours from the beginning of the operation. The product did not absorb oxygen.

The material obtained in this manner is soluble in benzene, xylene, chloroform and carbon disulfide, giving rich wine-red solutions; it is slightly soluble in warm acetone and is insoluble in ether, petroleum ether and gasoline. Several reprecipitations from benzene solution by petroleum ether gave a colorless amorphous solid, which decomposed at  $300^{\circ}$  to  $302^{\circ}$ . It is apparently identical with the products obtained under the other procedures. In no case could any peroxide be isolated.

As a final check upon the possibility of making the free radical by this last method, oxygen absorptions were taken on benzene solutions of chloride which had been boiled with copper bronze. At the end of the heating period the tubes containing the solutions were filled with benzene, cooled to room temperature and sealed. During the entire operation the solutions were under an atmosphere of dry hydrogen. The following measurements were made.

1.0169 g. of chloride, boiled for one hour, absorbed 25.2 cc. (N. T. P.) of oxygen, or 68.3% of the calculated quantity.

0.6516 g. of chloride, boiled for one hour, then allowed to stand for two hours at room temperature, absorbed 15.7 cc. (N. T. P.) of oxygen, or 66.5%.

0.7475 g. of chloride, boiled for three hours, absorbed 12.8 cc. (N. T. P.) oxygen, or 47.2%.

From these experiments we are inclined to conclude that the material obtained by Schlenk and Renning was not the free radical, phenyl-thio-xanthyl; and we believe that their values for the molecular weight and degree of dissociation of this radical should be rejected.

This investigation was made with the assistance of The National Aniline and Chemical Company Fellowship. We wish to express our obligations for the aid we have thus received.

### Summary.

The preparation of pure phenyl-thio-xanthenol chloride has been described. The free radical, phenyl-thio-xanthyl, has been prepared in solution and found to be very unstable, the rate of decomposition varying with the nature of the solvent. The radical could not be isolated in the solid state. It has been shown that the values obtained by Schlenk and Renning for the molecular weight of this substance were made on material which was in all probability not the free radical.

## 2,2'-SULFONIDO-TRIPHENYLMETHYL.

BY M. GOMBERG AND E. C. BRITTON.

Received June 8, 1921.

The chlorides of aryl xanthenols, aryl thio-xanthenols and aryl acridols are prepared from their corresponding hydrogen chloride additive compounds,<sup>1</sup> in which however the acid is held with considerable tenacity.

These normal chlorides are difficult to prepare in the pure state; the merest trace of moisture hydrolyzes them into carbinol and hydrochloric acid, the latter not escaping but being retained as the hydrochloride additive compound with the unhydrolyzed portion. In the process of the conversion of the carbinol chloride, contaminated in this manner, into the corresponding free radical the hydrogen chloride becomes liberated and tends to cause catalytic polymerization of the free radical. Herein may lie the reason why with this class of chlorides it has proved so difficult, and often wholly impossible, to isolate the free radical, notwithstanding the fact that the actual formation of the radical at the initial stage of the reaction could be demonstrated.

It seemed desirable to prepare a carbinol of bridged-ring type that would readily yield a stable chloride, one that would be devoid of the tendency to take on hydrogen chloride. Such a carbinol was found in 2,2'-sulfonido-triphenyl carbinol.<sup>2</sup>

**2,2'-Sulfonido-triphenyl Carbinol, (Formula II).**—This was synthesized by the following set of reactions: thio-xanthone, prepared by the condensation of thiosalicic acid and benzene in presence of sulfuric acid, was allowed to react with phenyl magnesium bromide, and the thio-xanthenol thus formed was oxidized to the sulfone.

<sup>1</sup> Gomberg and Cone, *Ann.*, 370, 142 (1909); 376, 183 (1910).

<sup>2</sup> The nomenclature here adopted is analogous to that suggested for phenyl-xanthenol, namely, 2,2'-oxido-triphenyl carbinol. Meyer and Jacobson's "Lehrbuch d. org. Chemie" Veit and Company, [II] 1914, Part 3, p. 765.

The thio-salicylic acid was prepared from anthranilic acid<sup>3</sup> with a yield of 80% to 90%. Thio-xanthone was prepared according to Smiles.<sup>4</sup> Fifty g. of thio-salicylic acid, 500 cc. of conc. sulfuric acid and 150 cc. of benzene were stirred for 10 hours; the reaction mixture was allowed to stand for 10 hours and finally heated for 1 hour on the water-bath. Water was then carefully poured over the surface of the acid and allowed to diffuse slowly, a procedure, we believe, first used by Graiebe. This gave a crystalline product which was easily filtered. The xanthone was purified by recrystallization from chloroform and then from acetic acid. Yield, 85%.

Phenyl thio-xanthenol (Formula I) was prepared from phenyl magnesium bromide and thio-xanthone,<sup>5</sup> and purified by recrystallization from petroleum ether, b. p. 100° to 110°. The yield of the pure product never fell below 90%.

For oxidation to the sulfone the following procedure was adopted. Twenty g. of phenyl-thio-xanthenol was dissolved in 140 cc. of hot glacial acetic acid, and 25.5 g. of chromic acid dissolved in 40 cc. of water was added at such a rate as to maintain the temperature above 100°. The reaction mixture was then heated for one hour on the water-bath; 50 cc. of hot water was added, and the solution was cooled. The precipitate was removed by filtration and was washed repeatedly with hot water to remove chromic acetate and chromic acid. For purification, the sulfonido compound was recrystallized from glacial acetic acid. Yield, 85%.

Hydrogen peroxide was tried as the oxidizing agent, but only a small quantity of the sulfone was produced, the chief product being a compound lower melting, presumably the sulfoxide, along with some benzophenone sulfone.

Another method for the preparation of the sulfone carbinol was devised, namely, the action of phenyl magnesium bromide on benzophenone sulfone. The benzophenone sulfone was prepared by the oxidation of thio-xanthone in acetic acid solution with 30% hydrogen peroxide according to the method of Ullmann.<sup>6</sup> 0.1 mol of powdered benzophenone sulfone was slowly added to an ether-benzene solution of 0.1 mol of phenyl magnesium bromide, and the solution was heated under a reflux condenser for one hour. The magnesium-bromide addition compound was decomposed by ice in the usual manner, and since the sulfone carbinol is insoluble in both ether and water, it was removed by filtration after neutralization of the magnesium hydroxide with hydrochloric acid. This method gives a 90% yield of fairly pure product, but the benzophenone sulfone which does not enter into reaction is not easily separated from the carbinol. For this reason, the first method of preparation is preferable.

*Analysis.* Calc. for  $C_{19}H_{14}O_3S$ : C, 70.77; H, 4.09; S, 9.95. Found: C, 70.67; H, 4.50; S, 9.93.

The sulfonido-triphenyl carbinol crystallizes in the form of needles and melts without decomposition at 224° to 5°. The compound is only slightly soluble in the

<sup>3</sup> Friedlander, 9, 542, Ger. pat. 205,450.

<sup>4</sup> Davis and Smiles, *J. Chem. Soc.*, 97, 1296 (1910).

<sup>5</sup> Gomberg and Cone, *Ann.*, 376, 203 (1910).

<sup>6</sup> Ullmann and Glenck, *Ber.*, 49, 2487 (1916).

usual organic solvents at ordinary temperature, although it can be recrystallized from a mixture of equal parts of chloroform and absolute alcohol. The sulfonido-carbinol dissolves in conc. sulfuric acid producing a red-brown solution, and may be recovered unchanged upon addition of water.

**2,2'-Sulfonido-triphenyl Methane,  $\text{SO}_2:(\text{C}_6\text{H}_5)_2:\text{CH}(\text{C}_6\text{H}_5)$ .**—Reduction with stannous chloride and hydrochloric acid converts the chloride into the methane compound, the sulfone group remaining unaltered. Two g. of the sulfonido carbinol was dissolved in 25 cc. of glacial acetic acid and reduced with 3 g. of stannous chloride dissolved in 25 cc. of acetic and 3 cc. of hydrochloric acid. The mixture was heated for 1 hour on the water-bath, diluted with 10 cc. of hot water, and then allowed to crystallize. The sulfonido methane was recrystallized from glacial acetic acid and was obtained in the form of colorless needles, m. p.  $193^\circ$  to  $194^\circ$ . The yield of pure product was 1.7 g. No color is developed by treating the methane with conc. sulfuric acid; it is not acted upon by phosphorus pentachloride nor is it oxidized back to the carbinol by chromic acid in acetic acid solution.

*Analysis.* Calc. for  $\text{C}_{19}\text{H}_{14}\text{O}_2\text{S}$ : S, 10.47. Found: 10.49.

**2,2'-Sulfonido-triphenyl Carbinol Chloride,  $\text{SO}_2:(\text{C}_6\text{H}_5)_2:\text{C}(\text{C}_6\text{H}_5)\text{Cl}$ .**—The carbinol chloride cannot be obtained by treating the carbinol with hydrogen chloride in ether or benzene solution, nor by boiling with acetyl chloride, thionyl chloride, or phosphorus trichloride, whereas practically nearly all the triaryl carbinols are converted to the corresponding chlorides by such treatment. Twenty g. of the carbinol was intimately mixed with slightly more than the theoretical quantity of phosphorus pentachloride (1 g. in excess) and the mixture was heated in an oil-bath at  $110^\circ$  to  $120^\circ$ . When the evolution of hydrogen chloride had commenced, the flask was removed from the oil-bath until the evolution of the gas had practically ceased, and the mixture was further heated for  $\frac{1}{2}$  hour. The phosphorus oxychloride was then distilled and the excess of phosphorus pentachloride was volatilized under reduced pressure by means of a current of dry air. The residue was dissolved in 75 cc. of hot benzene, filtered from some red precipitate, and the carbinol chloride was precipitated by the addition of 80 cc. of dry ligroin. For purification, the chloride was recrystallized from high-boiling ligroin ( $100^\circ$  to  $10^\circ$ ), the accompanying red impurity being entirely insoluble in this solvent, while the chloride is soluble to the extent of about 2 g. in 100 cc. Yield of pure product, 80%.

*Analysis.* Calc. for  $\text{C}_{19}\text{H}_{13}\text{O}_2\text{SCl}$ : C, 66.94; H, 3.84; S, 9.41; Cl, 10.41. Found: C, 66.65; H, 3.88; S, 9.42; Cl, 10.41.

The sulfonido-chloride melts without decomposition at  $160^\circ$  to  $1^\circ$ . It is readily soluble in benzene, chloroform, acetone, carbon tetrachloride, ethyl acetate, slightly soluble in ether, carbon disulfide, and practically insoluble in cold ligroin. It can be converted quantitatively into the carbinol by boiling with 80% acetic acid or diluted alcohol.

**The Free Radical, 2,2'-Sulfonido-triphenylmethyl  $\text{SO}_2:(\text{C}_6\text{H}_5)_2:\text{C}(\text{C}_6\text{H}_5)$ .**—The carbinol chloride employed for the preparation of the free radical was the purest possible, checked by its melting point and analysis. After many trials the following procedure was adopted. Two g. of the sulfonido-chloromethane and 12 g. of molecular silver (100 mesh) were placed in a 75cc. bottle, and enough benzene was added almost to fill the bottle, which was then tightly stoppered. After 35 minutes of vigorous shaking, the benzene solution was filtered into the standard apparatus,<sup>7</sup>

<sup>7</sup> Gomberg and Schoëpfle, *THIS JOURNAL*, 39, 1659 (1917)

and concentrated under reduced pressure at a temperature of 40°. Fifteen cc. of ether was then added to the sirupy residue in small portions, with shaking after each addition, and the free radical allowed to crystallize. After standing for 1 hour at 0°, the solvent was drawn off, the crystals were washed with ether and dried at a temperature of 40° for 1 hour. The yield of pure product was 1 to 1.3 g.

The free radical appears as a slightly yellow crystalline powder, which melts with decomposition at about 180°. It is soluble in all the usual organic solvents with the exception of ether, carbon disulfide, and ligroin, giving orange colored solutions, lighter in color than those of the radical phenyl-thio-xanthyl. When the free radical was recrystallized from carbon disulfide, the crystals formed did not lose all the carbon disulfide at any temperature below 80°, even under reduced pressure. Presumably a combination of free radical and solvent had occurred.

Calc. for  $C_{18}H_{18}O_2S$ : S, 10.50. Found: 10.57.

The procedure outlined above must be followed exactly in order to obtain a fair yield. If the weight of the silver is decreased, all of the carbinol chlorine will not be removed in a sufficiently short time, the same difficulty occurring if the silver is coarser than 100 mesh. If the time of shaking is prolonged, the product will absorb less than the theoretical quantity of oxygen, indicating decomposition of free radical. Indeed, shaking for one day with the quantities indicated will give a product entirely incapable of absorbing oxygen. Further than this, the free radical even in the solid state cannot be heated above 40° for any length of time without suffering some change.

**Oxygen Absorption and the Peroxide.**—When a solution of the free radical is exposed to oxygen or air a crystalline peroxide is formed and the solution becomes decolorized. The yield of the peroxide is usually 80 to 85%, just as has been found to be the case with triphenylmethyl and a number of other free radicals. The peroxide is insoluble in nearly all the organic solvents except chloroform, in which it is readily soluble, and benzene, in which it is slightly soluble. It crystallizes in the form of colorless needles, which melt with decomposition at 238° to 9°. It may be converted into the carbinol by heating at 100° with conc. sulfuric acid, the yield of carbinol amounting to about 40%.

Calc. for  $C_{38}H_{26}O_6S_2$ : C, 70.97; H, 4.08; S, 9.99. Found: C, 70.22; H, 4.26; S, 9.99.

In the formation of the sulfonido-triphenylmethyl peroxide from a solution of free radical the theoretical amount of oxygen is absorbed, two mols of the radical uniting with one mol of oxygen.

Oxygen absorptions were taken on the free radical produced in solution directly from the chloride as well as upon the previously isolated crystalline compound. In the former instance, the chloride was dissolved in bromobenzene, shaken with silver for 35 minutes in a sealed tube, and the absorption then taken after breaking the tube in the absorption apparatus connected with the gas buret. In addition, the yield of the peroxide formed was determined in each experiment.

Wt. of sample.		Cc	Oxygen. % of calc.	G.	Peroxide. % of calc.

<sup>a</sup> Absorption taken in benzene.

**Iodine Absorption.**—By adding a standard benzene solution of iodine to a benzene solution of the free radical, a titration may be accomplished, although the end point is rather indistinct, being observed in a brown solution. Two samples, 1.1000 and 0.7568 g. absorbed 0.412 and 0.298 g. of iodine, equivalent to 90.0 and 99.0%, respectively.

No attempts were made to isolate the unstable iodide. When the solution of the iodide is allowed to stand in air, iodine is liberated and large amounts of peroxide are formed.

**Molecular Weight Determination.**—Similar apparatus and manipulation were employed by us in the determination of the molecular weight of the free radical as previously described.<sup>8</sup> The samples used for the molecular weight determinations were all carefully dried under reduced pressure in an atmosphere of carbon dioxide at the temperature of boiling ether, and were in an inert atmosphere except during the short period of weighing. The determinations were carried out in an atmosphere of hydrogen to prevent oxidation of the free radical. Every sample to be used was analyzed as to its purity, and none was used which did not indicate an absorption of oxygen above 95% of that calculated. But two solvents were used, namely benzene and *p*-bromotoluene, giving temperatures of 5.4° and 27° respectively. The molecular depression constant for benzene was taken as 50 and for *p*-bromotoluene as 82.

At the completion of each molecular-weight determination the solution was exposed to air and the amount of peroxide formed showed that the radical had undergone practically no change in the process of the molecular-weight determination.

The results given in the following table indicate that there is little change in the molecular weight with increase in temperature from 6° to 27°, but there

<sup>8</sup> Gomberg and Schoepfle, *THIS JOURNAL*, 39, 1662 (1917).

is a remarkable change with increasing concentrations, the latter change however being somewhat irregular, and the results are possibly not so accurate as might be wished. The free radical, in solution, is evidently monomolecular to the extent of 30 to 38%, and dimolecular to 62 to 70%.

### Summary.

1. 2,2'-Sulfonido-triphenyl carbinol and the corresponding chloride were prepared. It was found that this chloride, unlike the chlorides of aryl thio-xanthenols, does not make additive colored compounds with hydrogen chloride.

2. The free radical, 2,2'-sulfonido-triphenylmethyl, was prepared. Its oxygen absorption, the degree of combination with iodine, and extent to which it exists as monomolecular have been determined.

ANN ARBOR, MICHIGAN.

## THE FRIEDEL AND CRAFTS' REACTION. BROMOPHTHALIC ANHYDRIDES, BENZENE AND ALUMINUM CHLORIDE.

BY H. N. STEPHENS.

Received June 8, 1921.

Rubidge and Qua<sup>1</sup> have studied the reaction between phthalic anhydride, benzene and aluminum chloride and have shown the conditions which will give a good yield of *o*-benzoyl-benzoic acid, and also the conditions which will give no acid and a 35% yield of diphenylphthalide. Lawrance,<sup>2</sup> who used the nitrophthalic anhydrides and the acetyl-amino-phthalic anhydrides in this reaction, points out that from each substituted phthalic anhydride there are possible two acid products and two derivatives of diphenyl-phthalide.

<sup>1</sup> Rubidge and Qua, THIS JOURNAL, 36, 732 (1914).

<sup>2</sup> Lawrance, *ibid.*, 42, 1871 (1920).

Two investigators have previously prepared *o*-benzoyl-bromobenzoic acid by this method. In 1879, nine years before Friedel and Crafts published their paper on the preparation of *o*-benzoyl-benzoic acid, Pechman<sup>3</sup> heated a mixture of bromophthalic anhydrides with benzene and aluminum chloride and obtained a product which he called *o*-bromobenzoyl-benzoic acid, m. p. 219° to 221°. This product was probably an impure specimen of 6-benzoyl-2-bromobenzoic acid, m. p. 231.5°. It will be noticed that, as Pechman used a mixture of the two bromophthalic anhydrides, there would be four possible products while he only described one. The results of the other investigator are given in a German patent.<sup>4</sup> He obtained two *o*-benzoyl-bromobenzoic acids, one from bromophthalic acid, an excess of aluminum chloride being used to dehydrate the acid, and the other from bromophthalic anhydride. The product from the latter melted at 174° and corresponds to that obtained by Kohler, Heritage and Burnley<sup>5</sup> by the oxidation of 2,6-dibromo-3-keto-1-phenyl-2,3-dihydrindene. As this product has been obtained in the present investigation from 4-bromophthalic anhydride and as the other product (m. p. 216° to 219°) more closely resembles the product from the 3-bromophthalic anhydride it might be inferred that a mixture of the bromophthalic acids was used in this case also. The present investigation was for the purpose of preparing and identifying the various *o*-benzoyl-bromobenzoic acids and the diphenyl-bromophthalides.

**3-Bromophthalic Acid.**—This acid has been prepared by Faust,<sup>6</sup> Pechman,<sup>3</sup> and Smith<sup>7</sup> but in each case the melting point is much too low and the product is evidently a mixture. Guareschi<sup>8</sup> oxidized 5-bromo-1-nitronaphthalene with potassium permanganate and obtained an acid melting at 174° to 176° but this method gave the writer only a 4% yield and the reduction of the 5-bromo-1-nitronaphthalene to 5-bromo-1-aminonaphthalene before oxidation did not improve the yield. The method finally adopted was the conversion of 3-aminophthalic acid into 3-bromophthalic acid by the Sandmeyer method. The aminophthalic acid was prepared as described by Lawrence.

Twenty-five g. of 3-nitrophthalic acid was reduced and the hydrochloride of the amino acid mixed with 200 cc. of 18% hydrochloric acid, diazotized, and poured into 150 cc. of a warm 10% solution of cuprous bromide. After warming gently on the water-bath to drive off oxides of nitrogen the solution was allowed to stand for several hours and a precipitate of *o*- and *m*-bromobenzoic acids was then filtered off and the filtrate extracted with ether, affording a yield of 28%. In this reaction a reddish oil is fre-

<sup>8</sup> Guareschi, *Ann.*, 222, 292 (1884).

quently obtained which may be removed by dissolving the acid in potassium hydroxide and oxidizing with potassium permanganate. The acid, recrystallized from water, melts at 177° to 8°.

*Analysis.* Calc. for  $C_8H_4O_4Br$ : Br. 32.6. Found: 32.4.

The anhydride was prepared from the acid by distillation and recrystallization from glacial acetic acid, m. p. 130–1°.

**4-Bromophthalic Acid.**—Nourrisson<sup>9</sup> prepared this acid from bromo-*o*-toluidine by converting it into the nitrile, hydrolyzing the nitrile and oxidizing the resulting bromo-*o*-toluic acid. Miersch<sup>10</sup> obtained the acid by oxidizing *p*-bromohydrindene with 25% nitric acid, and Perkin and Revay<sup>11</sup> oxidized bromo-indene with dil. nitric acid. The method finally adopted was that described by Armstrong and Rossiter<sup>12</sup> who oxidized 1,6-dibromo-2-naphthol and obtained a small quantity of 4-bromophthalic acid but give no quantitative details.

One hundred g. of  $\beta$ -naphthol was dissolved in 500 cc. of glacial acetic acid and a mixture of 223 g. of bromine and 100 cc. of acetic acid added. After standing overnight the crystals were filtered off, washed with water and dried in a vacuum oven at 70° for one hour. Evaporation of the mother liquor yielded more of the product. Recrystallized from 80% acetic acid the dibromo-naphthol melts at 106°; yield 90%.

Sixty g. of dibromonaphthol was dissolved in 1200 cc. of water containing 20 g. of potassium hydroxide, and 160 g. of potassium permanganate was added gradually with constant stirring, the temperature being kept low. After standing for 3 or 4 hours the solution was heated on the water-bath and potassium permanganate added gradually until a permanent pink color was obtained. The solution was then decolorized with ferrous sulfate, filtered, evaporated to 400 cc., acidified and extracted with ether. The product when recrystallized from water containing a few drops of sulfuric acid, melted at 170.5° and the yield of crude acid was 47% calculated on the dibromo-naphthol. The anhydride was prepared by distilling the acid; yield, 80%. The distillate was a white, crystalline mass, m. p. 104° to 106°. No solvent was found from which it could be recrystallized. On standing it changed slowly back to the acid.

### Reaction of 3-Bromophthalic Anhydride with Benzene and Aluminum Chloride.

Four and three-tenths g. of powdered 3-bromophthalic anhydride, 12 cc. of benzene and 5 g. of aluminum chloride were boiled for 4 hours on the water-bath under a return condenser. After the addition of 100 cc. of 10% hydrochloric acid the benzene was distilled with steam and the precipitate digested with a hot solution of sodium carbonate which left a slight residue of phthalide. The solution was diluted to about 250 cc. and very slowly acidified with 5% hydrochloric acid. If the acid is precipitated rapidly it separates as a gum which becomes crystalline only on long standing. The dry product was dissolved in 75 cc. acetone, 60 cc.

<sup>9</sup> Nourrisson, *Ber.*, 20, 1016 (1887).

<sup>10</sup> Miersch, *ibid.*, 25, 2115 (1892).

<sup>11</sup> Perkin and Revay, *J. Chem. Soc.*, 65, 253 (1894).

<sup>12</sup> Armstrong and Rossiter, *Ber.*, 24, ref. 705 (1891).

water added and the solution left overnight to crystallize. After several recrystallizations a constant melting point,  $231.5^{\circ}$ , was obtained. This substance is the only acid product of the reaction and is probably identical with the substance described by Pechman, m. p.  $219-21^{\circ}$ ; yield, 89%, calculated on the bromophthalic anhydride.

**Identification of the Substance Melting at  $231.5^{\circ}$ .**—Eight g. of potassium hydroxide was dissolved in a little water in a nickel crucible and 1 g. of the substance added. The mixture was slowly heated on a sand-bath, with constant stirring, and held at  $220-5^{\circ}$  for 25 minutes. After dissolving in water and acidifying, the precipitate contained benzoic acid and *o*-bromobenzoic acid. The substance is therefore, 6-benzoyl-2-bromobenzoic acid.

Calc. for  $C_{14}H_9O_3Br$ : Br, 26.2. Found: 26.1.

### Reaction of 4-Bromophthalic Anhydride with Benzene and Aluminum Chloride.

Four and three tenths g. of 4-bromophthalic anhydride, 12 cc. of benzene and 5 g. of aluminum chloride were boiled for 6 hours. The product of the reaction was obtained as in the previous experiment. The greenish gum given by the slow acidification of the sodium carbonate solution became crystalline on standing for a few hours; yield, 97%. The precipitate was washed, dried, dissolved in 40 cc. of alcohol, and water added just to turbidity. After standing for 12 hours in a covered dish the precipitate was filtered off and a second precipitate obtained by allowing the filtrate to stand for a day in an open dish.

After several recrystallizations the first fraction gave flat needles, soluble in ether and acetone, moderately soluble in alcohol, slightly soluble in hot benzene and insoluble in ligroin; m. p.  $193^{\circ}$ . This fraction was about 55% of the total yield of acids. The second fraction, after several recrystallizations, gave small rhombohedrons, m. p.  $172.5^{\circ}$ , very soluble in alcohol, ether and acetone, slightly soluble in hot benzene and insoluble in ligroin. This substance is, no doubt, identical with that described by Kohler, Heritage and Burnley<sup>5</sup> (m. p.  $174^{\circ}$ ) and with that described in the German patent.<sup>4</sup> This fraction represents about 45% of the total yield of acids.

**Identification of the Substance Melting at  $193^{\circ}$ .**—The substance was hydrolyzed by fusing with potassium hydroxide for 10 minutes at  $185-90^{\circ}$ . The fusion products were benzoic acid and *p*-bromobenzoic acid, and the substance is therefore 2-benzoyl-4-bromobenzoic acid.

Calc. for  $C_{14}H_9O_3Br$ : Br, 26.2. Found: 26.3.

**Identification of the Substance Melting at  $172.5^{\circ}$ .**—In the fusion of this substance the temperature was kept at  $170-5^{\circ}$  for 20 minutes. The fusion products were benzoic acid and *m*-hydroxybenzoic acid. As

*m*-bromobenzoic acid is changed to *m*-hydroxybenzoic acid by fusion with potassium hydroxide this identifies the substance as 6-benzoyl-3-bromobenzoic acid although Kohler, Heritage and Burnley described it as *p*-bromo-*o*-benzoylbenzoic acid.

### Reaction of 3-Bromophthalic Anhydride with Benzene, Aluminum Chloride and Acetic Anhydride.

Four and three tenths g. of 3-bromophthalic anhydride, 12 cc. of benzene and 5 g. of aluminum chloride were boiled for 4 hours and then 3 cc. of acetic anhydride and an additional 12 cc. of benzene were added, and boiling was continued for 3 hours. After treatment with sodium carbonate only a small quantity of insoluble material remained which on recrystallization from benzene melted at 148–50°.

As 3-bromophthalic anhydride gave only 6-benzoyl-2-bromobenzoic acid, only the diphenyl-bromophthalide corresponding to this acid is to be expected in the above reaction.

### Diphenyl-3-Bromophthalide.

Pechman<sup>13</sup> prepared diphenyl-phthalide from the mixed anhydride of *o*-benzoyl-benzoic acid and acetic anhydride with benzene and aluminum chloride. Following Pechman's method the anhydride of 6-benzoyl-2-bromobenzoic acid and acetic acid was prepared and then from it the corresponding diphenyl-bromophthalide.

Two g. of 6-benzoyl-2-bromobenzoic acid was heated on a water-bath with 4 cc. of acetic anhydride for 12 hours, and the liquid then poured into an equal volume of 95% alcohol. On standing for several hours a white crystalline substance separated which on recrystallization from alcohol gave fine colorless needles; m. p. 168.5°.

*Analysis.* Calc. for  $C_{16}H_{11}O_4Br$ : Br, 23.05. Found: 22.9.

One g. of this anhydride was heated with 5 cc. of benzene and 0.8 g. of aluminum chloride for 6 hours. After acidification the benzene was distilled with steam and the solid heated with sodium carbonate solution to remove acids. The insoluble residue was recrystallized from benzene and then from alcohol; m. p. 131°; yield, 71%.

*Analysis.* Calc. for  $C_{20}H_{13}O_2Br$ : Br, 21.9. Found: 20.4.

The very small quantity of the product, m. p. 148–50°, obtained from the 3-bromophthalic anhydride with benzene, aluminum chloride and acetic anhydride is not, therefore, diphenyl-3-bromophthalide.

### Reaction of 4-Bromophthalic Anhydride with Benzene, Aluminum Chloride and Acetic Anhydride.

Four and three tenths g. of 4-bromophthalic anhydride, 12 cc. of benzene and 5 g. of aluminum chloride were boiled for 6 hours, and then 3 cc. of

<sup>13</sup> Pechman, *Ber.*, 14, 1865 (1881).

acetic anhydride and 12 cc. of benzene were added and the boiling continued for 3.5 hours. After treatment with sodium carbonate the insoluble residues (diphenyl-bromophthalides) represented a total yield of 60%. This product was dissolved in a small amount of benzene and after standing for 24 hours gave a thick reddish liquid and a crystalline mass. The crystals after several recrystallizations from benzene melted at 186°. The reddish liquid was heated in a vacuum oven to remove benzene and the hard gummy residue was dissolved in a small quantity of hot alcohol, which on cooling deposited a reddish gum, but the remaining liquid after several hours gave a white crystalline substance which after several recrystallizations from methyl alcohol melted at 115–6°.

**Identification of the Diphenyl-bromophthalide, m. p. 186°.**—Two g. of 2-benzoyl-4-bromobenzoic acid was heated with 4 cc. of acetic anhydride for 4 hours on the water-bath. The solution was then poured into an equal volume of 80% alcohol and allowed to stand for several hours, when a gummy substance separated which on solution in hot alcohol, and cooling, gave a white amorphous powder; m. p. 83–7°. This powder with benzene and aluminum chloride gave a product, m. p. 186°, identical with one of those obtained from the 4-bromophthalic anhydride. It is, therefore, diphenyl-5-bromophthalide. Yield, 56%.

Calc. for  $C_{20}H_{13}O_2Br$ : Br, 21.9. Found: 21.8.

**Identification of the Diphenyl-bromophthalide, m. p. 115.6°.**—Two g. of 6-benzoyl-3-bromobenzoic acid was heated on the water-bath for 6 hours with 4 cc. of acetic anhydride. The product was then poured into double its volume of hot 50% alcohol and an oil separated on cooling. This oil did not crystallize after several precipitations from hot methyl alcohol but hardened to a gum with no definite melting point when dried *in vacuo*. This gum with benzene and aluminum chloride gave a product, m. p. 115–6°, identical with the product from 4-bromophthalic anhydride, benzene and aluminum chloride. It is, therefore, diphenyl-4-bromophthalide. Yield of crude material, 69%.

Calc. for  $C_{20}H_{13}O_2Br$ : Br, 21.9. Found: 22.1.

When 3-bromophthalic anhydride reacts with benzene and aluminum chloride only 6-benzoyl-2-bromobenzoic acid is obtained but when 4-bromophthalic anhydride is used approximately equal quantities of 2-benzoyl-4-bromobenzoic acid and 6-benzoyl-3-bromobenzoic acid are formed. The total yield in each case is good. The fact that only one product is obtained from 3-bromophthalic anhydride might be due to steric hindrance but Mr. Lawrance, in this laboratory, has found that the tetrahalogen-phthalic anhydrides with benzene and aluminum chloride give good yields of the benzoyl-tetrahalogen-benzoic acids.

Using benzene, aluminum chloride and acetic anhydride, 3-bromophthalic anhydride gave no diphenyl-bromophthalide, while a good yield

of both the possible diphenyl-bromophthalides was obtained from 4-bromophthalic anhydride. Oddy, working at McMaster University, has obtained good yields of the diphenyl-tetrahalogen-phthalides from the tetrahalogen-phthalic anhydrides.

### Summary.

1. Each of the two bromophthalic anhydrides has been found to react with benzene and aluminum chloride forming benzoyl-bromobenzoic acids. The 3-anhydride yielded only one acid while the 4-anhydride gave two in approximately equal quantities.

2. Under the conditions favorable to the production of diphenyl-bromophthalides, the 3-anhydride gave no diphenyl-bromophthalide while the 4-anhydride gave two.

3. A new method is described for the preparation of 3-bromophthalic acid and detailed directions given for the preparation of 1,6-dibromo-2-naphthol and 4-bromophthalic acid.

4. Seven new compounds have been prepared: 2-benzoyl-4-bromobenzoic acid, m. p. 193°; diphenyl-3-bromophthalide, m. p. 131°; diphenyl-4-bromophthalide, m. p. 115-6°; diphenyl-5-bromophthalide, m. p. 186°; mixed anhydride of 6-benzoyl-2-bromobenzoic acid and acetic acid, m. p. 168.5°; mixed anhydride of 2-benzoyl-4-bromobenzoic acid and acetic acid, m. p. 83-7°; and mixed anhydride of 6-benzoyl-3-bromobenzoic acid and acetic acid.

This research was carried out under the direction of Professor F. B. Allan. The writer held a bursary from the Honorary Advisory Council for Scientific and Industrial Research.

## THE ACTIVITY OF ADSORBED INVERTASE.

BY J. M. NELSON AND DAVID I. HITCHCOCK.

Received June 8, 1921.

The action on sucrose solutions of invertase adsorbed on charcoal and on gelatinous aluminum hydroxide was studied by Nelson and Griffin<sup>1</sup>. They reported that in their experiments a given quantity of enzyme exhibited the same activity when adsorbed on a solid in the bottom of the reaction vessel as when uniformly distributed throughout the solution. The importance of this observation and its bearing on the true nature of  
<sup>1</sup>Nelson and Griffin, *THIS JOURNAL*, 38, 722, 1109(1916).

enzyme action have been pointed out by Bayliss<sup>2</sup>, Lewis<sup>3</sup>, Falk<sup>4</sup> and others, and have led to the present further study of this phenomenon.

In some preliminary experiments with different charcoals it was found that in all cases where the invertase was completely adsorbed (or nearly so) there was a marked retardation of the hydrolysis. One charcoal was tried which caused very little retardation, but it was found that in this case the invertase was adsorbed only to a small extent. In order to determine whether the invertase was largely adsorbed or not, a mixture of sugar solution, adsorbent and invertase was prepared, shaken, and filtered about 10 or 15 minutes after the addition of the invertase. The absence of further change in the optical rotation of the filtrate indicated that the invertase had been completely adsorbed; much change in the rotation of the filtrate indicated incomplete adsorption. The retardation observed in the presence of the adsorbent could not have been due to changes in the hydrogen-ion concentration, since this was kept constant in all the experiments, both with and without adsorbent, by means of buffers. The result of a typical experiment with a charcoal of good adsorbing power are given in Table I.

TABLE I.  
Change in rotation.

Time, hours.	Filtrate.	Control (no charcoal).	Solution with charcoal.
18	0.40°	7.14°	2.03°
25.3	0.64	8.21	2.59
42.3	0.91	8.94	3.68

On testing the activity of invertase adsorbed on aluminum hydroxide, it was found that here too there was considerable retardation. It was thought that this might be due to the mechanical removal of the enzyme from the solution by the settling of the adsorbent. To test this explanation a mechanical stirrer was employed, which prevented the aluminum hydroxide from settling. It was found that the stirring prevented the greater part of the retarding action, as is shown by the results in Table II.

TABLE II.

Expt.	Sucrose conc., g. per 100 cc.	Time. Hours.	Filtrate.	Change in rotation.		
				Control.	With Al(OH) <sub>3</sub> . Stirred.	Not stirred.
20	5	1	0.00°	4.23°	3.82°	2.25°
21	10	1	0.01	4.53	4.18	3.61

From these experiments it was concluded that when an adsorbent is used without stirring, the rate at which the sucrose reaches the invertase is governed by the rate of diffusion of the sucrose down to the bottom of the vessel. Accordingly it was thought that if the action of the invertase

<sup>2</sup> Bayliss, "The Nature of Enzyme Action," 4th Ed., 1919, p. 112.

<sup>3</sup> Lewis, "A System of Physical Chemistry," 2nd Ed., Vol. I, 1918, p. 460.

<sup>4</sup> Falk, "The Chemistry of Enzyme Action," 1921, p. 61.

could be made even slower than the diffusion of the sucrose to the bottom of the reaction bottle, then there should be no retardation by the aluminum hydroxide. This was tried with 3 different invertase preparations by diluting the invertase to different degrees, with the results shown in Table III.

TABLE III.

Effect of Invertase Concentration on Retardation by Aluminum Hydroxide.

Expt.	Invertase conc. cc. per 100 cc. Prep. No. 1a	Time. Hours.	Filtrate.	Change in rotation.		Retardation by Al(OH) <sub>3</sub> , % of change in control.
				Control.	With Al(OH) <sub>3</sub> .	
22	2.50	18	0.00°	3.10°	2.78°	10
25	1.25	18	0.07	1.51	1.52	00

Prep. No. 8.						
27	1.00	1	0.05	6.79	4.68	31
28	0.10	12	0.05	6.97	5.58	20
31	0.05	12	0.00	3.66	3.20	13
32	0.025	24	0.01	3.65	3.47	5
30	0.01	24	0.01	1.43	1.45	0
Prep. No. 10.						
41	2.50	24	0.11	3.83	3.38	12
43	1.25	24	0.05	1.38	1.29	7
44	0.50	24	0.02	0.75	0.73	3
44	0.50	48	0.01	1.38	1.37	1
44	0.50	96	0.01	2.45	2.47	0

It seems from these figures that the absence of retardation observed by Nelson and Griffin is not general, but represents only a very special case. Probably in most of their work the action of the enzyme was slower than the rate of diffusion of the sucrose. The slow rate of reaction in their second series of experiments<sup>5</sup> indicates that this explanation may apply there.

In some of the experiments with charcoal reported by Griffin and Nelson in their first paper,<sup>6</sup> the rate of reaction seems not to have been very slow. Since they gave no measurements of the inverting power of the filtrates in these experiments, it is possible that the absence of retardation may have been due to incomplete adsorption of the invertase by the charcoal. The present authors are unable to explain the earlier experiment<sup>7</sup> with aluminum hydroxide at hydrogen ion concentration  $5.0 \times 10^{-7}$  in which it was shown that the invertase was completely adsorbed. Repetitions of this experiment at about the same rate of inversion have indicated a retardation by aluminum hydroxide.

<sup>5</sup> *Loc. cit.*, p. 1110.

<sup>6</sup> *Ibid.*, p. 727.

<sup>7</sup> *Ibid.*, p. 729.

### Experimental Details.

**Materials.**—The invertase was prepared from yeast by the method of Nelson and Born<sup>8</sup> omitting the second and final precipitations by alcohol. Preparation 10 was obtained by dissolving 0.570 g. of the solid Invertase A of Nelson and Vosburgh<sup>9</sup> in 500 cc. of distilled water.

Suspensions of aluminum hydroxide prepared from the chloride could not be used; the precipitate so made either clogged the filter or ran through in a turbid colloidal suspension and did not completely adsorb the invertase. The aluminum hydroxide finally used was prepared from alum as described by Welker and Marshall,<sup>10</sup> and was washed repeatedly by decantation and also by dialysis for 2 days against running water. The suspension contained 0.0205 g. of aluminum oxide in 5 cc. In each experiment 100 cc. of the reaction mixture contained 5 cc. of this suspension.

The charcoal used in the experiment of Table I was an imported decolorizing powder; 100 cc. of the reaction mixture contained 0.30 g. of charcoal. In other experiments samples of this charcoal which had been boiled with hydrochloric acid or ammonium hydroxide and then washed caused the same retardation as the untreated charcoal.

The cane sugar was used the best commercial grade, as was that used by Nelson and Griffin.

**Control of the Hydrogen-ion Concentration.**—The buffer used in the experiments with charcoal was a mixture of secondary sodium citrate and hydrochloric acid.<sup>11</sup> It was found that the aluminum hydroxide did not completely adsorb the invertase in the presence of a citrate buffer at  $P_H = 4.45$  (or a phosphate buffer at  $P_H = 6.3$ ); accordingly for the experiments with aluminum hydroxide a buffer mixture of acetic acid and sodium acetate was prepared.<sup>12</sup> In all experiments the reaction mixture was 0.01 *M* with respect to total electrolyte. In the experiments of Tables I, II, III the hydrogen-ion concentration was  $10^{-4.4}$  to  $10^{-4.5}$  moles per liter, which is the optimum for invertase action.<sup>13</sup> The hydrogen-ion concentration was measured by the colorimetric method using  $\alpha$ -naphthyl-amino-azo-*p*-benzene sulfonic acid as indicator with citrate standards, which were standardized electrometrically using the saturated potassium chloride calomel cell.<sup>14</sup> The hydrogen-ion concentrations were based on 0.1000 *M* hydrochloric acid as a standard, its ionization<sup>15</sup> being taken as 91.7% at 37°.

**Procedure.**—The method of experimentation was similar to that of Nelson and Vosburgh,<sup>9</sup> but in accordance with the recommendation of Vosburgh<sup>16</sup> the dilution of the invertase with anything except water was avoided until the time for starting the reaction. The invertase was diluted with distilled water to twice the strength required, and to start the reaction, it was mixed with an equal volume of a double strength

sugar solution containing buffer, either with or without charcoal or aluminum hydroxide. The concentration of sucrose in the reaction mixture was 10 g. per 100 cc., except in Table I and Expt. 20, Table II, where it was 5 g. per 100 cc. The inversions were allowed to take place in Nonsol glass bottles in a thermostat at  $37^{\circ} \pm 0.02^{\circ}$ . Bacterial action was avoided by keeping the solutions saturated with toluene. The reaction was stopped and mutarotation hastened by the use of sodium carbonate,<sup>17</sup> a 25cc. sample being added to 5 cc. of 0.1 *M* sodium carbonate solution. For the measurements of rotation the solutions were put into 200mm. tubes in the thermostat described by Nelson and Beegle,<sup>18</sup> which remained at  $25^{\circ} \pm 0.05^{\circ}$ . Readings were taken with a Schmidt and Haensch polarimeter which could be read and set to  $0.01^{\circ}$ . Light of wave length  $546 \mu\mu$  was used, being obtained from a mercury-vapor arc lamp and purified by a Wratten filter, No. 74.

Initial rotations were measured in samples in which the sodium carbonate was added before the invertase, which was thus rendered inactive so that no inversion took place. Identical values for the initial rotation were obtained in samples in which the aluminum hydroxide was mixed with the sugar solution before measuring out a sample of the latter and in others in which no aluminum hydroxide was used; this indicates that the volume occupied by the precipitate was negligible, and that no appreciable amount of sugar was adsorbed by it.

Solutions for the control experiments were made up with aluminum hydroxide, which was removed by filtration before the addition of the invertase. To determine whether the invertase was really adsorbed under the conditions of each experiment, a duplicate solution was prepared from which the adsorbent was filtered off about 10 or 15 minutes after the beginning of the reaction. Then a sample was taken, and the completeness of adsorption was determined by the absence of further change in rotation from that time on for a time equal to the duration of the main experiment.

In working with fairly rapid inversions, such as those in Table II, it was possible to obtain duplicate results which checked to  $0.02^{\circ}$  or better. With very dilute invertase, however, the agreement of the duplicates was worse, some differing by as much as  $0.1^{\circ}$ . This irreproducibility seems to be due to the effect of dilution noticed by Vosburgh.<sup>16</sup>

### Summary.

1. A comparison has been made of the amount of sucrose hydrolyzed in a given time by invertase combined with an adsorbent and not combined but uniformly distributed throughout the solution.

<sup>17</sup> Hudson; *THIS JOURNAL*, 30, 1564 (1908).

<sup>18</sup> Nelson and Beegle, *ibid.*, 41, 559 (1919).

2. When all conditions were the same except the presence or absence of the adsorbent and the velocity of hydrolysis was relatively large, then the amount hydrolyzed in a given time was less in the presence of the adsorbent.

3. The decrease in rate appears to be due largely to the uneven distribution of the invertase in the reaction mixture, because by preventing the settling of the adsorbent combined with the enzyme the extent of the retardation was diminished.

4. When the velocity of hydrolysis is relatively small then it is practically the same irrespective of whether the enzyme is combined with aluminum hydroxide or not. As a tentative explanation it is suggested that under these conditions the rate of diffusion of the sucrose to and the invert sugar from the enzyme combined with the adsorbent is probably greater than the rate of hydrolysis of the sucrose.

5. No evidence has been obtained so far which indicates that the true activity of the invertase, as distinguished from the resultant rate of hydrolysis of the sucrose in the mixture, is influenced by the combination of the invertase with the adsorbent.

The authors wish to express their indebtedness to the Harriman Research Laboratory, New York City, for grants in aid of this investigation.

## DERIVATIVES OF 2,4,6-TRINITRO-BENZALDEHYDE.<sup>1</sup> II.

BY ALEXANDER LOWY AND WILMER BALDWIN.

Received June 18, 1921.

In the previous report,<sup>2</sup> the object of the research and references to the literature were given together with the theoretical phase of the subject.

The reactions investigated were all of the general type of condensations previously described<sup>3</sup> for the preparation of modified "Schiff's bases."<sup>3</sup> Condensations were carried out between 2,4,6-trinitro-benzaldehyde and the following substituted amines: *o*-anisidine, *p*-anisidine, *o*-phenetidine, *p*-phenetidine, *o*-chloro-aniline, *p*-chloro-aniline, and 2,4-dichloro-aniline.

### Experimental Part.

**Preparation of 2,4,6-Trinitro-benzaldehyde.**—The method used in the preparation of this compound was essentially that described by Sachs

<sup>1</sup> This report represents an abstract of a thesis presented by Wilmer Baldwin in partial fulfillment of the requirements for the degree of Master of Science, June, 1921.

<sup>2</sup> THIS JOURNAL, 43, 341 (1921).

<sup>3</sup> *Ber.*, 35, 984 (1902).

and Kempf and Everding.<sup>4</sup> Certain modifications of this method worked out by Lowy and Balz<sup>5</sup> in these laboratories were followed.

The table below contains an abstract of the results obtained.

Product.	M. p. ° C.	Color.	RESULTS. Crystallizing medium.	Calculated.	Found.	Calculated.	Found.
				% N.	Analysis. %.	% Cl.	%.
2,4,6-tri-nitrobenzal- <i>o</i> -phenetidine	178.5	yellow	alcohol	15.56	15.50 15.63		
2,4,6-tri-nitrobenzal- <i>p</i> -phenetidine	177	light orange	alcohol	15.56	15.60 15.45 15.30		
2,4,6-tri-nitrobenzal- <i>o</i> -anisidine	171.5	yellow	chloroform	16.19	16.04 16.10		
2,4,6-tri-nitrobenzal- <i>p</i> -anisidine	182	yellow	chloroform	16.19	16.01 16.24		
2,4,6-tri-nitrobenzal- <i>o</i> -chloro-aniline	187	yellow	acetone	15.98	15.94 15.80	10.11	10.00 9.98 9.82
2,4,6-tri-nitrobenzal- <i>p</i> -chloro-aniline	180	yellow	acetone	15.98	15.97 16.03	10.11	9.87 9.92 9.87
2,4,6-tri-nitrobenzal-2,4-dichloro-aniline	198	yellow	acetone	14.81	14.90 14.63	18.42	18.08 18.22 18.24

In the preparation of compounds listed above the ratio of one mole of 2,4,6-trinitro-benzaldehyde to one mole of the substituted amine was used in all cases. Glacial acetic acid or hot alcohol was used as condensing agent in all the above preparations. These products are soluble in acetone, chloroform and benzene and insoluble in water. On hydrolysis with 1:1 hydrochloric acid they yield 2,4,6-trinitro-benzaldehyde and the respective amines.

When the condensations of 2,4,6-trinitro-benzaldehyde and *o*-chloro-aniline, *p*-chloro-aniline, and 2,4-dichloro-aniline were carried out in hot glacial acetic acid solution, orange colored products were obtained, with melting points in all cases approximately 100° higher than those of the products prepared in the cold acetic acid solution. These compounds are insoluble in many solvents except glacial acetic acid. Preliminary work seems to indicate that they are dimolecular condensation products as exemplified by the following types. One molecule of 2,4,6-trinitro-benzaldehyde may be made to condense with 2 molecules of *tertiary* alkylated aromatic amines, substituted aromatic amines, or phenolic.

<sup>4</sup> Sachs and Kempf, *Ber.*, 35, 1236 (1902); Everding, *ibid.*, 36, 960 (1903).

<sup>5</sup> Lowy and Balz, *THIS JOURNAL*, 43, 343 (1921).

bodies to produce derivatives of triphenyl methane. Danckwortt<sup>6</sup> condensed *p*-nitrobenzaldehyde with phenolic bodies. Since these condensations present possibilities for the preparation of dyes they are now being investigated.

The above tabulated list of compounds like many other similar condensation products are affected to a considerable extent by the action of light. It was noted that the halogenated derivatives were particularly susceptible to light.

PITTSBURGH, PENNA.

## NOTES.

**The Enzymes of the Abdominal Adipose Tissue of the Common Turkey, Meleagris Gallopavo.**—While the constants of turkey fat have been studied by several investigators, the enzymes, which occur in the adipose tissue (crude fat), have not been studied. Such a study, made upon samples of known history, is reported in this paper. The turkeys were hens, grown and killed in central Tennessee. They were marketed during the Christmas season. In trade parlance, they were dry picked, air chilled, well bled, undrawn (uneviscerated) birds. After slaughter, they were kept in a mechanically refrigerated chill room or cooler at a temperature of approximately 0° for 3 days, then were shipped to this city by express, two days being required for the journey. Upon arrival at Philadelphia, they were again placed in a mechanically refrigerated chill room, in which they were kept at a temperature of approximately 0° for from 3 to 7 days; they were then removed for study.

An aqueous extract of the abdominal adipose tissue (crude gizzard fat) was prepared as in the studies of chicken fat by Pennington and Hepburn.<sup>1</sup> The technic in the test for lipase, esterase, catalase, reductases, oxidase, and peroxidase was that used in the studies cited with the following modifications. Tributyrin was used as a substrate for lipase, and ethyl butyrate for esterase. In testing for catalase, 20 cc. of the aqueous extract was taken; and the volume of the evolved oxygen was recorded without correction. As reagents for oxidizing enzymes, use was made of  $\alpha$ -naphthol, trikresol, and phenolphthalin; when phenolphthalin was the substrate, 0.1 *N* sodium hydroxide solution was added after incubation until the phenolphthalein present showed its maximum red color.

The proper control experiments were always made on the boiled aqueous extract in order to allow for all changes in the substrate not due to enzyme action. Trikresol was used as a bactericide at a concentration of 0.2% in the tests for lipase, esterase, simple reductase, and protease.

<sup>6</sup> Danckwortt, *Ber.*, **42**, 4163 (1909).

<sup>1</sup> Pennington and Hepburn, *THIS JOURNAL*, **34**, 210 (1912); *Bur. Chemistry, Circ.*, **75**, 1 (1911); **103**, 6 (1912).

The results of the tests for *lipase*, *esterase*, *catalase*, *simple reductase*, and *aldehyde reductase* have been collected in the table; a plus + indicates the presence, a zero (0) the absence of reductase.

TABLE I.

Occurrence of Certain Enzymes in the Abdominal Adipose Tissue of the Common Turkey.

Expt. Number.	Lipase.	Esterase.	Catalase.		Reductase.	
			Cc. O <sub>2</sub> evolved.			
	Cc. 0.1 N butyric acid. Liberated in 72 hours.		30 min.	Time. 24 hours.	Simple.	Aldehyde.
Hen.						
1.....	2.20	....	12.7	39.0	+	....
2.....	5.35	1.25	10.8	....	+	0
3.....	4.90	0.35	....	7.9	+	0
4.....	6.40	0.85	....	22.5	+	Trace
5.....	6.80	0.80	....	31.4	+	Trace
6.....	4.70	0.40	....	2.0	0	0

**Oxidases** acting upon trikresol and upon  $\alpha$ -naphthol were not found. All but one of the samples contained an oxidase acting upon phenolphthalin. One sample was also tested for cresol tyrosinase,<sup>2</sup> the oxidase which produces colored compounds by its action on a mixture of *p*-cresol and amino acids or secondary protein derivatives; the substrates used were trikresol plus asparagin and trikresol plus Witte peptone; both tests were entirely negative.

**Peroxidase** acting upon  $\alpha$ -naphthol occurred in one sample, and peroxidase acting upon phenolphthalin was found in another sample. Peroxidase acting upon trikresol was not detected.

**Protease.** Two of the samples were tested for the presence of a protease. The results indicated that such an enzyme, active in the presence of hydrochloric acid, did not occur in the adipose tissue.

A 20cc. portion of the aqueous extract of one sample was permitted to act upon a flock of carmine fibrin in the presence of 0.2% hydrochloric acid; the fibrin was not attacked after incubation for 24 hours at a temperature of 37.5°.

A 2.5cc. portion of the aqueous extract of another sample was mixed with 2 cc. of a 2% solution of castor bean globulin in 5% sodium chloride solution; and 0.5 cc. of 0.1 N hydrochloric acid was then added. The precipitated protean, derived from the globulin, was not attacked during incubation for 7 days at a temperature of 37.5°.

### Summary.

Catalase, lipase (acting on tributyrin), and esterase (acting on ethyl butyrate) were always found in the adipose tissue. Simple reductase

<sup>2</sup> *Arch. sci. phys. nat.*, [4] 33, 70 (1912).

and oxidase acting upon phenolphthalin were usually present. Tests for oxidases, which act on  $\alpha$ -naphthol and on trikresol, and for protease gave negative results. Aldehyde reductase and peroxidases were found in several of the samples.

**Friedel and Crafts' Reaction. The Preparation of 2-*para*-Toluyyl-Benzoic Acid.**—In order to determine whether the results obtained by Rubidge and Qua<sup>1</sup> in the study of the reaction between phthalic anhydride, benzene and aluminum chloride are of general application the reaction between phthalic anhydride, toluene and aluminum chloride has been studied. In the following table the yields are calculated on the phthalic anhydride used.

No.	Toluene. G.	Phthalic anhyd. G.	AlCl <sub>3</sub> G.	Time. Hrs.	Toluyylbenz. acid. %.	Ditolyl- phthalide. %.
1	20	5	9	12	89	5.4
2	20	5	9	12	92.5	3.9
3	43	5	9	12	90	5
4	20	5	9	12	95	1.9
5	20	5	10	10	97	trace
6	20	5	4.5	12	19	34
7	20	5+5	9	12+12	19	27
8	20	5+5 cc. acet. anh.	9	12-12	none	52
9	20	5+3.2 cc. acet. anh.	9	12-12	none	45

Nos. 1 and 2 show that using the proportions of the reagents indicated the yield of toluyyl-benzoic acid is about 90%, and that some ditolyl-phthalide is formed. In No. 3 the increased amount of toluene did not materially affect the yield. In No. 4 the aluminum chloride was finely powdered and in No. 5 the slightly larger amount of aluminum chloride prevented the formation of any ditolyl-phthalide. In No. 6 with half the usual amount of aluminum chloride the yield of acid is greatly reduced and ditolyl-phthalide increased. In No. 7 the usual proportions of the reagents were used, but after 12 hours' boiling additional phthalic anhydride was added and boiling continued for 12 hours. The results show that the additional phthalic anhydride reacted with the intermediate compound to give ditolyl-phthalide. Nos. 8 and 9, with acetic anhydride used instead of the additional phthalic anhydride after the first 12 hours' boiling, gave no toluyyl-benzoic acid and a better yield of ditolyl-phthalide.

These results agree completely with those obtained by Rubidge and Qua.

## NEW BOOKS.

**The Chemical Effects of Alpha Particles and Electrons.** By SAMUEL C. LIND, Ph.D., Physical Chemist, U. S. Bureau of Mines. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 1 Madison Avenue, New York, U. S. A., 1921. 182 pp., 7 figs. 23.5 X 15.5 cm. Price \$3.00.

The first numbers of the American Chemical Society's Monograph Series will meet an inspection which will not be accorded their successors. Hence it is gratifying to see as the second of the series this able and scholarly treatise on a subject which otherwise would hardly have found a publisher.

Much in it will be new to most chemists. It deals with work which is midway between chemistry and physics, and thus has attracted only a relatively small number of investigators who are masters of both. Chemists have too generally regarded it as physics, and indeed the methods of physics are largely in evidence. Yet it is one function of that science to furnish ever new tools for the fundamental investigations of other sciences and, since the time of Lavoisier's use of the balance, chemistry has taken on new vigor with each successive adaptation of the physicist's methods. The active chemist must keep his eyes open to such possibilities, as the work of Ramsay and of Lind testifies, and as every reader who feels the inspiration of this book will admit; for we have here the application of an entirely new form of energy to the production of chemical reactions, and energy in a uniquely measurable and mechanically definite form. We are largely free from thermodynamics and statistical averages. The energy input is mechanically visible, and gives great promise of a mechanical visualization of the course of the reaction produced. The observation is intimate.

The first three chapters are devoted to an exposition of the physics involved—radioactivity and the nature of gaseous ionization. The next three record early studies of radiochemical action in gases and liquids. Then follow three chapters on the mechanism of radiochemical reactions, and in particular, the relation between gaseous ionization and chemical action, which has been the special problem of Dr. Lind himself, and which furnishes the most promising generalization in this subject, namely that for most reactions a single pair of ions corresponds to the transformation of one molecule. The exact study of the relation between ionization and consequent reactions still has a long future.

There follows an equally interesting discussion of the photochemical equivalence law. The still doubtful subject of action by positive rays and recoil atoms is discussed in Chapter XI, and the book closes with a review of Rutherford's work on the disintegration of other atoms by  $\alpha$  particles.

It should be noted that the chemical effects of electrons are hardly touched on, the vast amount of study on reactions in the various types of electron discharge being quite without the scope of this book. Indeed, the

reactions which are discussed are merely the most promising because the most intimately known of all the reactions which are produced by gaseous ionization. Chemists still need a careful analysis of the whole subject of electron effects.

Dr. Lind has given us a readable, authoritative, and complete discussion of his subject. He deserves the thanks of American chemists.

GERALD L. WENDT.

**Priestley in America, 1794-1804.** By EDGAR F. SMITH, University of Pennsylvania. P. Blakiston's Son and Company, 1012 Walnut Street, Philadelphia, Pennsylvania. 1920. i + 173 pp. 12 X 18.5 cm. Price \$2.00 Net.

On the evening of the fourth of June, 127 years ago, the 60-year old Joseph Priestley, a passenger in the good ship *Sansom*, landed in New York. Of the earlier life in England of this man, who was primarily an educator and a theologian, and not a chemist, but who, like his friend Franklin, was many-sided and had an intense curiosity regarding the secrets of nature, Thorpe has given us an adequate picture.<sup>1</sup>

In this book Dr. Smith gives us an account of the last 10 years of Priestley's life, a record of especial value not only to chemists but to all interested in the religious thought, educational ideas, and politics of this period. Contemporary letters, newspapers, and pamphlets are drawn upon largely for the story of this decade, and the excerpts throw an interesting light not only upon Priestley but upon the young republic in its experimental stage.

Priestley was warmly received on his arrival in New York as a chemist and as a leader who stood for political and religious freedom. Among the welcoming addresses was one from the Tammany Society of New York which will be to many a revelation regarding that organization. His influence was soon felt in education, and to American science the prestige of the discoverer of oxygen and the founder of pneumatic chemistry gave new impetus.

He was the friend and correspondent of Silliman of Yale, Mitchell of Columbia, McLean of Princeton, Thomas Cooper, professor of Chemistry at the University of Pennsylvania and at Carlisle, Woodhouse and the other Philadelphia chemists.

The most certain contribution to experimental chemistry from his laboratory in Northumberland was the preparation of carbon monoxide (1799), the constitution of which was clearly shown by Clément and Dé-sormes in 1801, but much of his scientific energy was spent in the defence against his American critics of his beloved phlogiston theory to which he clung to the last.

<sup>1</sup> "Joseph Priestley," T. E. Thorpe, London, 1906.

The author deals lightly with Priestley's political views. That he was a caustic critic is evident. He was out of patience with the public measures of the country. He disliked them as much as he did those of England, but added "here the excellence of the constitution provides a remedy, if the people will make use of it, and if not they deserve what they suffer."

President Adams had joined in welcoming Priestley to the new world, but they were too diametrically opposed both in religion and politics, and the friendship waned, assisted possibly by the fact that Priestley's friend Cooper was sentenced to prison in 1801 for libeling the President.

Priestley, the teacher, had many valuable ideas on education and his letters to his friend Thomas Jefferson, with whom he had much in common are decidedly interesting. They have much to do with the founding of the new college which the latter contemplated for the State of Virginia, but no inducements could win Priestley back to his early profession, and his modesty regarding his own attainments and ability as an instructor in chemistry is shown in a very candid letter refusing the professorship of Chemistry at the University of Pennsylvania.

His greatest interest was in religious matters, and he can be regarded as the first great exponent of Unitarianism in the country. By word and pen he was constantly engaged in theological discussion and exposition, a field which he regarded as his great life work. The rôle of Priestley, as a metaphysician and materialist, the exponent of a new philosophy, has been little touched upon in this volume.<sup>2</sup>

In this memoir of Joseph Priestley, Dr. Smith has made a valuable contribution to the history of chemistry in America and has fulfilled in a delightful way the wish of Harriet Martineau in her *Retrospect of Western Travel*.

"Of his retirement in America we have many particulars, but still not enough. Enough can never be learned of the course of life of one whose more homely virtues were now put to the severest test, after those which are commonly esteemed more loftily had well stood their trial."<sup>3</sup>

F. B. DAINS.

**Practical Biological Chemistry—"Guide pour les Manipulations de Chimie Biologique."**

By GABRIEL BERTRAND and PIERRE THOMAS of the Institute Pasteur. Translated from the third edition by Hector A. Colwell, M. B., D. P. H. Harcourt, Brace and Howe. New York, 1921. xxxii + 348 pp. 61 figures. 14 × 22 cm.

While the title of this volume implies its dedication to Biological Chemistry, the authors have been by no means restricted to this field. Chapters are devoted to the isolation and detection of the alkaloids, to the elements

<sup>2</sup> Prof. Woodbridge Riley ("American Thought," 1915, p. 100); "American Philosophy, The Early Schools," 1917, p. 107.

<sup>3</sup> "Retrospect of Western Travel," by Miss Martineau. p. 178.

of microbiology, glucosides, essential oils, and the description of the terpenes. Further, scattered throughout the text are a large number of directions for qualitative and quantitative procedures which, strictly speaking, fall far outside the range of Biological Chemistry.

The grouping of the subjects is widely different from that usually adopted in text-books written in English, and while the system gives the student a varied experience, there is not the same degree of logical development of the science which might result from a profound rearrangement of the subject matter. The grouping of the "Estimation of Tannin in Tanning Material" and of the "Ethereal Sulfates in the Urine" is but one illustration chosen at random. As is to be expected a relatively large amount of space is devoted to the sugars, but the quantitative methods, outside of the use of the polariscope, are confined to those suggested by the senior author. In the same way exception may be taken to the determination of such important compounds as urea, only the hypobromite method being discussed and that by means of the Bertrand method, without mention of the several other types of apparatus. The chemistry of the blood is largely ignored, that of the urine most imperfectly treated, such methods as are described being chiefly historical in interest. The newer colorimetric and nephelometric methods are not touched upon.

The translator states in his preface that the somewhat diffuse character of the subject matter is of value, as it is thus able to reach the physician, physiologist, bacteriologist, botanist, agriculturist, and those who are applying science to the furtherance of commercial enterprise. In the reviewer's opinion this constitutes a decidedly negative feature, as to cover these fields adequately means a work of far greater scope than that under consideration. Furthermore, it would mean for each of the workers listed above the necessity of searching through a considerable amount of material not germane to any of the problems arising in his special field in order to find the small amount of pertinent information.

In spite of the comparatively recent date of issue the book reminds one most strongly of those spuriously compendious treatises designed for the use of medical students in which was attempted a conspectus of the entire fields of chemistry and physics. As these encyclopedic volumes have been gradually replaced by specialized texts, so this book would seem to have been superseded by the very excellent and not over-bulky texts now available in the several fields. For the more comprehensive and exhaustive study such treatises as Abderhalden's "Biochemischen Arbeitsmethoden" are available.

In conclusion it may be said that the translation is apparently an excellent one, being clear and terse.

ALLAN WINTER ROWE.

**The Chemistry of Synthetic Drugs.** Third edition, revised. By PERCY MAY, D.Sc. (Lond.), F.I.C. Longmans, Green and Company, Fourth Avenue and 30th Street, New York, 1921. xv + 248 pp. 14 × 22.5 cm. Price, \$4.25 net.

This new edition of "The Chemistry of Synthetic Drugs" is practically identical with the second edition. It is unfortunate that in putting out a third edition, more effort has not been made to bring it up to date, by mentioning a number of substances which have excited considerable interest among chemists and which have proved of value to medical men, even though some of these substances could not yet be called large sellers from a commercial standpoint. In particular might be mentioned "Thyroxin," the trade name for the essential constituent in thyroid gland extract. Still another is "Apothesin," the hydrochloride of  $\gamma$ -diethyl-amino-propyl cinnamate, a local anesthetic used in place of procaine. It is true that this substance is inferior to procaine, but the fact that it is sold in large quantities and widely distributed makes it deserving of mention. No reference is made to benzyl benzoate or to other benzyl esters which have found such a wide and successful use in the United States as anti-spasmodics. This list could be extended to include several others of less importance which have, however, become large items in the lists of various manufacturers, such as "Oxyl-Iodide," the hydro-iodide of cincophen, "Chloroxyl," the hydrochloride of cincophen, and "Mercurochrom," the disodium salt of dibromo-hydroxy-mercury-fluorescein. All of these substances are synthetics which have attracted more especial attention in the United States during the last three years. Undoubtedly others of real and permanent importance have been discovered and marketed in European countries, but a knowledge of them has not yet become general in this country.

The new points in this edition are a page devoted to a description of "eccaine," a new local anesthetic of complex nature made from certain decomposition products of cocaine, and a few additional sentences of which one concerning mustard gas and a second concerning trinitrotoluene may be mentioned.

For those who are not acquainted with this book by Percy May, it may be said that it presents in a concise and readable form the fundamental facts about the majority of important synthetic drugs and extracted substances which have proved valuable in the medical profession. Methods of preparation are discussed and uses noted. The book may be highly recommended to any one who wishes to acquire a general knowledge of this field.

ROGER ADAMS.

**Organic Medicinal Chemicals (Synthetic and Natural).** By M. BARROWCLIFF and FRANCIS H. CARR. Industrial Chemistry Series, edited by Samuel Rideal. D. Van Nostrand Company, 8 Warren Street, New York, N. Y. 1920. xiii + 331 pp., 24 figures. 14 × 22 cm. Price, \$4.00.

This volume deals with a phase of the chemistry of medicinal drugs

which has never before been emphasized and will be very useful to organic chemists and to pharmacologists who desire to know how the substances which he uses are produced on a large scale. The authors deal very briefly indeed with the pharmacological action of the substances considered and the book is in no sense a text-book of pharmacology. However, the pharmacological statements are in the main sufficiently accurate. The writers discuss briefly in connection with each type of drug the relation of chemical constitution to pharmacological action. The main emphasis is placed upon the methods of large scale production, and the text contains many figures illustrating the types of apparatus used. The book should tend to stimulate the interest of the organic chemists in the synthesis of medicinal substances and also interest of students in the methods used in the large scale production of organic medicinal drugs.

A. S. LOEVENHART.

**Chemistry Review Book—Including Recent Examination Questions.** By M. H. KESSEL, B.S., Science Master in the Clark School for Concentration, New York City. Globe Book Company, New York, 1921. 96 pp. 16 figures. 15.5 × 23 cm. Price, \$0.67.

This little book is a careful compilation of definitions, equations, and laws together with very brief statements in regard to properties, uses, and processes which the student is most likely to need in preparing for an examination in chemistry. In this field the book will probably serve a useful purpose. It is the best of its kind that we have seen.

#### THE CATALYTIC OXIDATION OF CARBON MONOXIDE.<sup>1</sup>

By T. H. ROGERS, C. S. PIGGOT, W. H. BÄHLKE AND J. M. JENNINGS.

Received July 12, 1920.

#### Introduction.

This problem was a phase of the War Gas Investigations and was undertaken at this laboratory<sup>2</sup> early in May 1917, under the auspices of the U. S. Bureau of Mines, with the object of providing a mask ingredient which would afford protection against carbon monoxide when present in air. The desired application and the necessary specifications of such a material having been described<sup>3</sup> in detail, the present article presents, from the chemical standpoint, the most important features of the development of a suitable oxidizing catalyst.

#### General Statement.

† work was done in making comparative tests of the materials of the literature as capable of oxidizing carbon monoxide at various pressures,<sup>4</sup> always with the object in view of ultimately making a selection, by permission of the Director of the Chemical Warfare Service. The investigation was directed by Professor J. C. W. Frazer, who is one of the authors of the general article, Lamb, Bray and Frazer, *J. Ind. and Eng. Chem.*, 12, 1920, concerning the treatment of this problem as a whole by various laboratories with the Central Laboratory at Washington. See also Frazer, *ibid.*, 13, 1921, and Frazer, Ref. 2. See also von Kralitz, "Handbuch d. anorganischen Chemie," on carbon monoxide.

the reaction catalytic. It was observed while doing this preliminary work that many of these substances when intimately mixed gave a material much more active than any one of its constituents. For example, while neither chromium trioxide,  $\text{CrO}_3$ , nor yellow mercuric oxide oxidized carbon monoxide appreciably when a low concentration of this gas in air was passed through a tube containing these materials, a mixture of the oxides containing chromium trioxide, in excess of equivalent proportions was found to possess considerable oxidizing power and about 50% of the carbon monoxide was oxidized for a short period.

Again, silver oxide which oxidizes carbon monoxide only slowly at room temperatures, when mixed in various proportions with calcium hydroxide showed markedly greater activity, evidencing the increased activity of mixtures over that of single constituents. Other important factors, more or less self-evident, in the use of mixtures of two or more substances are the fineness of subdivision and intimate admixture of these substances, the resulting product being essentially a solid solution in certain cases. When a mixture of silver and calcium hydroxides was prepared by the simultaneous precipitation of the hydroxides from a water solution of the nitrates of these metals, and the precipitate washed and dried at  $120\text{--}130^\circ$  in a current of oxygen a material was obtained having marked activity. When dried in a current of air or oxygen the color of this mixture at times changed during the process of drying from a light brown to a slate color, a color change which indicates the decomposition of the silver oxide. On examination it was found that globules of metallic silver could be seen in the material. This decomposition was observed at  $100^\circ$  in the air and at  $130^\circ$  in oxygen, whereas the decomposition pressure of silver oxide is but 0.2 atmospheres at  $130^\circ$ . This notable increase in the decomposition pressure of silver oxide is being investigated further to determine whether the phenomenon is due to fineness of subdivision or to some other cause connected with the presence of calcium hydroxide, one effect of which may be to prevent the increase in size of the silver oxide particles.

The activity of these mixtures of silver oxide and calcium hydroxide was slightly increased by the addition of a small quantity of sodium hydroxide. The oxidation of the resulting material (about 80% for 20 min) was entirely due to the combined oxygen, as the amount of oxygen consumed was never more than could be accounted for by the silver oxide.

Manganese dioxide was ultimately found to be an essential part of the best catalysts, and here also the same general statement may be applied. Mixtures of manganese dioxide and silver or calcium hydroxide were found to be much more active towards carbon monoxide than the oxides used separately. The addition of a third component, sodium hydroxide, was advantageous in the preliminary experiments. The action of these mixtures containing sodium hydroxide was

not catalytic. They functioned for only about 40 minutes under the testing conditions given below and the amount of oxidation was not greater than could be accounted for by the active oxygen contained in the material. The behavior of these mixtures is shown in Table I.

It was not until finely divided manganese dioxide was prepared, and special precautions, listed later, were used to secure the admixture therewith of other oxides, that the catalytic oxidation of carbon monoxide at room temperature was satisfactorily solved. The most satisfactory catalysts were obtained by using a mixture containing either silver oxide or copper oxide and manganese dioxide. Of these mixtures those containing silver oxide seemed to be more active than those containing copper oxide. Other oxides such as iron oxide may be tolerated in certain amounts in the final products, but such oxides seem to act more as inert diluents and decrease rather than increase the activity of the material. However, when catalysts are prepared by properly mixing manganese dioxide with both silver and copper oxides such catalysts may be quite as active as those containing either copper or silver oxide alone.

The conclusions reached from the preliminary work on manganese dioxide were, first, that the degree of subdivision was an extremely important factor in the activity of this material; and, second, that the activity is also greatly increased by properly incorporating with finely divided manganese dioxide, other metallic oxides such as copper and silver oxides.

A comparative study was then made of samples of manganese dioxide prepared by the following methods.

1. **Reduction of Potassium Permanganate by Methyl Alcohol.** (a)—When a warm solution was reduced, the manganese dioxide particles were comparatively coarse, settling rapidly, and the mixtures prepared from such materials were not very active (Table I (a)). When the reduction was brought about in a cold solution a more flocculent precipitate was obtained which settled more slowly than (a), and it will be seen by referring to Table I that the silver oxide mixtures were more active than similar mixtures made from samples (a).

The mixtures of silver oxide and manganese dioxide made from both (a) and (b) above were quite efficient in bringing about the oxidation of carbon monoxide for an hour or more and the oxygen consumed was greater than the available oxygen of the material, showing these samples to be partially catalytic. The active zone of the material at any time during the test could be immediately ascertained by the location of the warm portion of the tube. This zone moved along gradually as the efficiency of that portion dropped and finally passed to the bottom of the tube, when carbon monoxide could be detected in the effluent gas. Prior to this, however, the action was 100 % efficient.

2. **The Frémy Method.**<sup>5</sup>—One hundred g. of finely ground potassium permanganate is added to 500 g. of conc. sulfuric acid in 150 cc. of water, cooled, carefully stirred, and allowed to stand, when the permanganic acid formed decomposes, giving off oxygen. Permanganic anhydride,  $Mn_2O_7$ , will sometimes separate as an oil which is extremely

<sup>5</sup> Frémy, *Compt. rend.*, 82, 1213 (1876). We are indebted to W. A. Patrick for suggesting this method of preparation.

explosive. When all the permanganic acid is decomposed the manganese dioxide is washed in a large quantity of water by decantation until free from sulfates. At the final washing the precipitate approaches the colloidal condition and settles very slowly. The manganese dioxide still contains a small quantity of a potassium salt, which is evidently very strongly adsorbed. The oxide mixtures prepared from this grade of manganese dioxide were truly catalytic, and, when tested on dry gas, showed that a layer only about 1 cm. deep was entirely efficient in oxidizing carbon monoxide. This method of preparation of manganese dioxide was generally used in the work of development of the optimum proportions of the constituents.

**3. Electrolytic Method.**<sup>6</sup>—This consists in the electrolytic oxidation of manganese in an ammonium carbonate solution using a ferromanganese alloy as the anode. The ammonium permanganate formed decomposes with the precipitation of finely divided manganese dioxide. When a 2-component cell is used this decomposition takes place best at temperatures slightly above 40°. When a 1-compartment cell is used oxidation and reduction take place simultaneously, thus permitting lower temperatures and consequently finer manganese dioxide. The material so produced was not uniform but the best preparations were very active.

**4. Reduction of Permanganic Acid by Oxalic Acid.**—Permanganic acid, prepared from the calcium salt is diluted with a considerable quantity of water, well cooled and a cold solution of oxalic acid is added in slight excess. As carbon dioxide is the by-product, no washing is necessary. This manganese dioxide with silver oxide produced a catalytic material of unlimited life.

**5. Decomposition of Ammonium Permanganate.**—One hundred g. of calcium permanganate is dissolved in 500 cc. of water, and ammonium carbonate solution containing a little ammonia is added. Calcium carbonate is filtered off, and the ammonium permanganate, diluted to 4 liters, is reduced slowly in the cold with methyl alcohol. This method gives very finely divided manganese dioxide and yields uniformly active catalysts of unlimited life. It is probably superior to that prepared by Method 1, because ammonium salts are less strongly adsorbed than are potassium salts.

**6. Air Oxidation of Manganese Oxide.**—The probable mechanism of catalytic oxidation by manganese dioxide, *viz.*, oxidation and reduction of the oxides of manganese, indicated that a catalyst might be prepared from manganous hydroxide and its oxidation effected before use, by drying in atmospheric oxygen. Manganous and silver oxides, precipitated simultaneously from a solution of the nitrates, were dried in oxygen at 130°; a number of mixtures of moderate life were thus produced, but the product was not of uniform activity. Results using copper oxide were less encouraging.

**Preparation of Catalytic Material.**—The oxide catalysts were prepared by the following method, which was used quite generally throughout the investigation whenever the solubilities of the salts used permitted. Manganese dioxide paste of known water content (60–65%) was weighed and suspended in a large volume of cold water, care being taken to secure a uniform suspension; to this was added a standard silver nitrate solution sufficient to give the desired amount of silver oxide in the final mixture. After thorough mixing silver hydroxide was precipitated by a slight excess of sodium hydroxide solution, with constant stirring. After filtering and washing free from sodium nitrate, the mixture was dried on a water-bath and then at about 125° in air or, preferably, in dry oxygen. The drying

<sup>6</sup> This method was developed by B. F. Lovelace.

must be quite thorough, otherwise the mixture will not function catalytically.

Copper oxide cannot be incorporated with manganese dioxide by the above method and a good catalyst obtained, but by using the method of precipitating with a sodium carbonate solution as described below an excellent catalyst may be made containing only manganese dioxide and copper oxide.

An important variation of the above method consisted in the precipitation of silver (or copper) as carbonate, rather than the oxide. During the subsequent drying the carbonate hydrolyzed almost completely, so that what was essentially the oxide mixture was finally produced, similar to the above but more active, especially in the case of mixtures containing only copper oxide and manganese dioxide. When 3 component mixtures were prepared (silver oxide, manganese dioxide and cupric oxide) the nitrates of copper and silver were added to the suspension of manganese dioxide.

It has been stated that Methods 2, 4 and 5 produce the most suitable manganese dioxide for a catalytic material when mixed with other oxides. The relative activities of the different samples were better shown when the amount of silver oxide in the material was reduced (Table III). The most effective mixture prepared according to Method b contained 62.5% of silver oxide, while with that made by Methods 2, 4 and 5 the silver oxide content was successfully reduced to 37.5%, and to 28% when the silver was precipitated as carbonate. The 3-component mixtures (silver oxide, cupric oxide and manganese dioxide), described above, were developed with a practical end in view, *i. e.*, to reduce the cost of the catalyst. In this connection the precipitation as carbonates was especially valuable and, as stated above, the silver oxide could then be completely replaced by cupric oxide when using manganese dioxide prepared by the Frémy method.

Special tests on the most active 2-component catalyst (62.5% of manganese dioxide, 37.5% of silver oxide) are of interest. After a 10-hour test on 1% carbon monoxide with 100% efficiency, the material was allowed to cool and a 0.3% carbon monoxide mixture run in at the same rate (500 cc./min.). The warm area (about 0.5 cm. in length) immediately reappeared at the same place and remained stationary for 10 hours longer, no carbon monoxide at all being detected in the effluent gases at the end of this time. The "pick up" of the catalyst was excellent; as the material was found to function at even lower than room temperature, there was no initial period of low efficiency while the catalyst was warming up.

#### Effect of Humidity.

Inasmuch as these catalysts were to be used for military and naval purposes under all weather conditions with varying temperatures

and humidities, the effect of these factors was of considerable importance.

At low temperatures a poor catalyst was less active, but a good catalyst would give 100% efficiency immediately, under varying concentrations of carbon monoxide at all temperatures covered in any tests,  $-5.0^{\circ}$  being the lowest temperature used. The greater the concentration of carbon monoxide (the rate of flow being the same) the more the catalyst would automatically heat up. The most active catalysts were exposed to both high (2% to 5%) and low (0.08% to 0.1%) concentrations of carbon monoxide at temperatures ranging from  $+100^{\circ}$  to  $-5^{\circ}$  without any detectable loss of efficiency.

With water vapor the case was quite different. As has been indicated above, the deleterious effect of moisture was recognized early in the investigations while working out the best conditions of drying the first catalysts produced. Samples which were not entirely dry possessed little or no activity, while a good dry sample broke down when exposed to any appreciable quantity of water vapor. However, a catalyst which had been rendered inactive in this way could be "regenerated" by drying at  $130^{\circ}$  in a stream of dry air or oxygen. From the military point of view this effect of moisture was of great importance and efforts were made to combat it. This effect of water vapor is a necessary result of the fine structure of the catalyst, and is obviously due to condensation in the pores of the material.

The ordinary mixture is rather soft and very porous and has a low apparent density. However, if this material be put in a press while still moist and subjected to a high pressure (2819 kilograms per sq. cm.) the apparent density is greatly increased and the resultant cake when dried, is relatively hard and quite resistant to crumbling, which in itself is of great importance in the military canister. A material so treated is more resistant to moisture and will last longer than the same volume of the unpressed material against a gas mixture of a given humidity. Tests were made on both pressed and unpressed catalysts at relative humidities from 25% to 100%, the pressed material in each case having a somewhat longer life.

#### Methods of Testing and Analysis.

The standard test prescribed by the Bureau of Mines was used throughout, except in special cases. This consisted in passing the air-gas mixture at the rate of 500 cc. per sq. cm. of cross section per minute through a layer of the catalyst 10 cm. deep. This corresponds to a rate of 32 liters per minute for a canister of regulation size, and is about twice the average rate of breathing.

The standard concentration was 1.0%, regulated by mixing pure carbon monoxide and air in the proper proportion through flow meters. For the catalyst, glass tubes were used having 1 sq. cm. cross sectional area, the granular material to be tested being poured in and the tube gently tapped to cause moderate settling.

The catalyst before being tested was broken up and screened and that portion which passed through the 10-mesh sieve and was retained by the 20-mesh was used. Conditions in a canister are more favorable than those of the tube test, since in a layer of broad cross sectional area there is less channeling of the gases and the loss of heat by radiation is less.

Samples, 500 cc. in volume, of the gases issuing from the test-tubes, were taken in glass bottles by displacement of water. A sample was taken immediately after the run was started and at regular intervals (usually 10 minutes) thereafter. These samples were analyzed by the iodine pentoxide method, consisting of passing the gases over a considerable quantity of pure iodine pentoxide at 160°. The gases from the sample bottle were passed successively through standard barium hydroxide, over calcium chloride, iodine pentoxide, and finally through potassium iodide solution and then through barium hydroxide. The barium hydroxide was titrated with standard oxalic acid, and in this way the quantity of carbon monoxide oxidized by the catalyst and that oxidized by the iodine pentoxide was determined, thus furnishing a check on the analysis. This method of analysis is quite accurate and, by using a large quantity of iodine pentoxide can be made with reasonable rapidity. Frequent analyses of the gases passing effluent to the flow meters were made as a check on the flow meters.

## Discussion.

The present investigation relates entirely to experiments which were made for the purpose of affording protection against the poisonous action of carbon monoxide. It was done under the stress of war conditions when no opportunity was afforded to investigate the mechanism of the reactions involved. The physical structure of the oxides in the catalysts described is an essential factor in their activity; this matter is now being investigated by a careful study of their adsorption isotherms. However, certain facts were noted in the course of this work which appear to have relation to a possible chemical explanation of the reaction. The fundamental assumption of such an explanation is that the oxygen used for the oxidation of the carbon monoxide comes immediately from the oxide catalyst, and that in turn the catalyst is reoxidized by the oxygen of the air sufficiently rapidly to maintain its oxygen content and high activity. As the catalysts are mixtures of more than one oxide it is a question which of these plays the principal rôle. Since both silver oxide and manganese dioxide as prepared above will oxidize carbon monoxide at room temperature, either may be considered as the initial cause of the reaction. But both of these oxides when used alone suffer loss of oxygen, soon lose their activity and are not catalytic in their action. Copper oxide does not oxidize carbon monoxide at an appreciable rate at room temperatures. As the catalysts described above all contain manganese dioxide as an essential constituent, and as the physical condition of the manganese dioxide is of paramount importance it

is assumed on the basis of the above facts that the manganese dioxide is the initial cause of the oxidation, probably functioning by reason of the variable valence of the manganese. Manganese dioxide prepared by any method yielding relatively coarse particles has very slight activity, whereas if its particles are practically of colloidal dimensions it uniformly produces a satisfactory catalyst. Fine subdivision of the particles of the other constituents and their intimate contact with the manganese dioxide particles tend of course toward the production of the most reactive material. On the basis of this explanation of the reaction, the single oxides are not reoxidized by oxygen fast enough to maintain catalytic action; the function of the other oxide or oxides is to increase the velocity of reoxidation of the manganese dioxide, and for this purpose silver oxide appears to be more efficient than copper oxide. In support of this view is the fact that a material prepared by simultaneous precipitation of manganous and silver hydroxides can be made very reactive by air oxidation at 125°. Of course the alternative is to assume that silver or copper oxide is the immediate cause of the action and that manganese dioxide catalyses the reoxidation of the reduced oxides. In favor of this assumption is the fact that manganese dioxide is a good catalyst for the decomposition of such metallic oxides as those of silver and mercury. The present work furnishes no proof of either view, and until further observations on the behavior of these oxide mixtures are available both views are tentative.

Another fact related to the intermediate oxide theory is that a mixture which is partially catalytic, as is the case when the catalyst is not sufficiently active or when the catalyst is poisoned by water vapor, always loses "available" oxygen. The first explanation of the poisonous effect of water vapor would be that the loss of activity results from a diminution of the large internal surface, so essential in these catalysts, which is in part covered by liquid water. This, however, seems hardly to account for all the facts, since under these conditions the catalyst suffers reduction, therefore the carbon monoxide in the mixture has access to the catalyst. The loss of activity seems to result, therefore, primarily from the inability of the catalyst surface to recombine with oxygen. It is possible that this is due to a condensation of water within the pores of the catalyst which thereby separates the oxide particles and thus prevents the intimate contact of the oxides which is essential for the catalytic activity of the material. Some of these points are under investigation, and it is realized that a further discussion is premature until these results, especially those bearing on the adsorption of these catalysts, are available.

The use of these oxides as catalysts is naturally not limited to carbon monoxide, but may be applied to a number of other substances; further work along these lines is in progress, including the oxidation of ammonia. The range of applicability is quite wide, especially in the field of organic oxidations, depending of course, on the possibility of carrying out the

reaction in the vapor phase. It has been found that the action is too energetic in some cases, but the possible variations in physical properties and in constituents present many possibilities, as is illustrated by the varying degrees of activity toward carbon monoxide observed in the various mixtures during the present investigation. Thus the degree of catalytic activity may be adapted and controlled to suit the conditions of each oxidation reaction.

### Summary.

1. The decomposition temperature of silver oxide when simultaneously precipitated with calcium hydroxide is considerably lower than that of silver oxide alone.

2. A number of catalysts have been prepared which cause rapid and complete oxidation, at ordinary temperatures, of carbon monoxide in any concentration at which sufficient oxygen is present.

3. The essential constituent of this class of catalysts is specially prepared manganese dioxide, upon which is precipitated the oxide of silver or copper or both.

4. The silver or copper is best precipitated as the carbonate, and subsequently hydrolyzed to the oxide.

5. The presence of water vapor limits the life of these catalysts.

6. The application of this class of catalysts to a number of oxidation reactions is suggested.

In conclusion the authors desire to pay full tribute to Professor Frazer, to whom principally the success of this investigation is due, whose resource and pertinacity were a source of inspiration to those associated with him.

## THE CATALYTIC OXIDATION OF CARBON MONOXIDE AT ORDINARY TEMPERATURES.

BY DAVID R. MERRILL AND CHARLES C. SCALIONE.

Received March 2, 1921.

The experimental work upon which this paper is based was done by the authors and their associates largely for the purpose of developing a suitable absorbent for carbon monoxide for use in gas masks,<sup>2</sup> and, because of the importance of obtaining production on a large scale without delay, it was not possible to investigate the scientific aspects of the problem as thoroughly as could be desired. An endeavor has been made in the preparation of the present paper to choose, from the large mass of data obtained,

<sup>1</sup> Published with the permission of General Amos A. Fries, Chief of the Chemical Warfare Service.

<sup>2</sup> An historical review of the investigations connected with the problem of the carbon monoxide mask giving due credit to the various persons concerned has been published by A. B. Lamb, W. C. Bray and J. C. W. Frazer in the *J. Ind. Eng. Chem.*, 12, 213 (1920).

such typical data as are of scientific interest, and to present them for the use of other investigators in this field.

It is well known that, in spite of the large decrease in free energy in the oxidation of carbon monoxide by atmospheric oxygen, the rate of this reaction at room temperature is entirely negligible in the absence of catalysts. The activity of platinum and palladium blacks in catalyzing this reaction has long been recognized, but no examples of active catalysts containing only the more common metals were found in the literature at the time the present investigation was begun. The work of Wright and Luff<sup>3</sup> on the minimum temperature of reaction of carbon monoxide with various metallic oxides had indicated the possibility of preparing oxides of sufficient activity<sup>4</sup> for use as oxidizing agents in carbon monoxide masks, although these investigators did not conduct their experiments in such a way as to show whether or not the oxidation would be catalytic in the presence of excess of oxygen.

The present investigation was undertaken in an endeavor, by suitable variation of the chemical composition and physical properties of mixtures of metallic oxides, to prepare a solid substance which would oxidize dilute carbon monoxide—air mixtures with reasonable completeness at ordinary temperatures and fairly high rates of flow. These properties are of course more essential in a practical absorbent than is catalytic activity. Because of the desirability of the latter, however, the choice of materials for experimentation was based both on the suggestions obtained from the work of Wright and Luff and on the chemical theory of catalysis. According to this theory the catalyst actually takes part in the reaction, oxidizing the carbon monoxide and being itself reoxidized by the oxygen of the air. In order that this may take place it is necessary that the oxide be readily reduced and also that in its lower state of oxidation it be readily oxidized. Suitable couples of higher and lower oxide or oxide and metal are more likely to be found where more than one oxide of the metal is known than where the metal is readily oxidized to a single oxide. By the application of these ideas, it was found possible to prepare oxide mixtures (called for convenience Hopcalite or HC<sup>5</sup>), which catalyze the oxidation of dilute carbon monoxide—air mixtures at ordinary temperatures<sup>6</sup> for

an indefinite length of time when protected from moisture, as by a layer of calcium chloride in the canister.

### General Description of the Catalysts.

An absorbent, to be suitable for use in gas-masks, must have a very high activity in proportion to its volume.<sup>4</sup> Since, in heterogeneous catalysis, the amount of reaction that a catalyst is able to bring about is a function of the surface exposed, it was important to prepare the catalysts in a form exposing the maximum surface, and this was accomplished by preparing the oxide mixtures in the form of porous granules. The use of ignited oxides was not satisfactory because of their low activity at ordinary temperatures. Precipitated oxides were found to be more active, but granules prepared by simple drying and crushing of the filter cake were often lacking in mechanical strength; and no binders were found that did not materially reduce the activity of the resulting product. It was found, however, that fairly hard granules could be obtained by careful control of the conditions of precipitation, and that the hardness could be further increased by submitting the filtered precipitate to high pressure in a hydraulic press before drying.

Among the various oxides and mixtures investigated there were two mixtures which were particularly active, and it was these which were studied in most detail. The first will be referred to as the 4-component mixture (or Hopcalite I) and consisted of approximately 50%  $\text{MnO}_2$ , 30 %  $\text{CuO}$ , 15 %  $\text{Co}_2\text{O}_3$  and 5 %  $\text{Ag}_2\text{O}$ . About 7,300 kg. of this mixture was produced on the large scale and used to fill about 40,000 canisters.<sup>7</sup> The second mixture, referred to as the 2-component mixture, consisted ordinarily of 60 %  $\text{MnO}_2$  and 40 %  $\text{CuO}$ , and, although somewhat cheaper, was developed too late for use on the large scale.

For use in gas masks, the granules were screened between 8- and 14-mesh screens, as this range of sizes gave a suitable balance between excessive pressure drops from fine granules on the one hand, and poor efficiencies due to channeling and mechanical leakage with thin layers of comparatively coarse granules on the other. The color of the granules of either mixture is a brownish black, and most samples are abraded somewhat more readily than the army soda-lime. An investigation made by G. A. Hulett of the porosity of a sample of 4-component mixture, 14-16 mesh, gave the results indicated below. The apparent density of the granules was 0.501 g. per cc. The true density of the solids was determined from the actual volume displaced, after evacuation under water to displace the air in the capillaries by water, and was found to be 5.65 g. per cc. The granules were then centrifuged to remove the excess water but leave that filling the capillaries. This latter was determined from the

<sup>7</sup> Lamb, Bray and Frazer, Ref. 2, p. 220.

increase over the original dry weight, and amounted to 88 cc. per 100 g. This is equivalent to 8.8 cc. of solids, 44.2 cc. of capillary voids and 47 cc. of gross voids per 100 cc. of granules. This is a high degree of porosity<sup>8</sup> and results in the catalysts being excellent absorbents for organic compounds of high molecular weight such as some of the war "gases."

**Factors Influencing Activity.**—The factors influencing the activity will be discussed in detail in connection with the preparation of the individual oxides, but it may be said that in general the activity of the mixtures is dependent upon the preparation of the individual oxides in a high state of oxidation and a suitable physical condition. The complexity of the problem of determining the effects of the various factors may be judged from the number of variables which must be considered. The more important of these are as follows: the choice of the constituents of mixtures of oxides and the methods of preparation of the individual oxides; the completeness of washing of the precipitates; the methods of mixing and filtration; the kneading and high-pressure filtration or other treatment of the wet cake; the conditions of drying and final moisture content; and the size of granules and method of utilization of fines. The activity is also dependent upon the conditions of test, such as the temperature, moisture content, concentration and rate of flow of the gas.

**Methods Used in Testing the Catalysts.**—The activity of the catalysts at room temperature was determined by the use of apparatus of the same general design as that used in testing other absorbent materials for use in gas masks. The glass tube containing the sample had a cross sectional area of about 1.5 sq. cm. and the normal depth of layer used was 5 cm. Free radiation was permitted from the tube and most of the tests were made with a room temperature of 25°. The carbon monoxide was prepared either by the action of sulfuric acid on formic acid or by the reduction of carbon dioxide by charcoal in a tube furnace. The standard rate of flow of the carbon monoxide—air mixture through the absorbent was 500 cc. per minute per sq. cm. of gross area, which, with a depth of layer of 5 cm. is equivalent to a space velocity of 6000 cc. of gas mixture per hour per cc. of catalyst. Most of the tests were made using a 1% mixture although some were made with 0.15 % or 0.25 % to determine whether the reaction would start properly with such dilute gas. The influent gas was analyzed occasionally and the effluent gas continuously by means of the Lamb and Larson calorimetric device<sup>9</sup> which was found very convenient for the purpose. The device was calibrated frequently by comparison with analyses by the iodine pentoxide method.

For the tests with dry gas, the mixture was passed through two bead towers, into which conc. sulfuric acid dripped. For the tests with humidity another pair of towers was used and dil. sulfuric acid of the proper concentration to give the required vapor pressure of water. The activity specifications for the material prepared on the large scale have been already recorded.<sup>7</sup>

The apparent density of the granules was determined from the weight of 50 cc. measured in a special tube which permitted a standard degree of packing to be obtained. The hardness or resistance to abrasion the granules was determined by a method similar to that used for soda-lime. This consisted in shaking a weighed amount of the granules with steel balls in a pan on a Rotap machine for a definite length of time, removing the balls and weighing the granules retained on a 20-mesh screen. The percentage retained was called the hardness number. The time of shaking was chosen so as to give numbers between 50 and 80 for the majority of samples, as the results were more reproducible within this range. The values so obtained are only relative and cannot be compared directly with those for the somewhat harder army soda-lime where the standard time of shaking was longer.

#### **Standard Methods of Preparation of the Oxides and Mixtures.—**

As a guide to those who may wish to prepare these catalysts for experimental purposes, the methods used in their preparation on the small scale will be given in detail. On the large scale the methods were essentially the same except in the case of the manganese dioxide. With this oxide it was difficult to reproduce small-scale conditions, and some variations were therefore necessary in adapting the process to large-scale production. The methods used in the preparation of the 4-component mixture will be described first.

*Preparation of Manganese Dioxide.*—One hundred and fifty g. of finely ground anhydrous manganese sulfate is mixed rapidly with 142 g. of water in a container arranged for cooling and thorough mechanical agitation. Without further delay 675 g. of 93% sulfuric acid is added with constant agitation. This produces a fine suspension of manganese sulfate in about 77 % sulfuric acid. As soon as the temperature falls to 50°, 150 g. of potassium permanganate is added in small portions at a time in the form of a coarse powder. The addition should take 15 to 20 minutes and the temperature should not rise above 75°. After about 10 minutes more at 60° the reaction is practically complete and the mixture is poured in a fine stream into about 25 liters of water with thorough agitation, and washed by decantation until free of sulfates. Yield, 100 to 125 g.

On the large scale the chief difficulty experienced was in obtaining proper temperature control due to the large amount of heat given off by the reaction and the high rate at which it is given off when the reaction once

starts. This difficulty was overcome by the use of steam in the cooling coil for the first three minutes in order to give a local high temperature and insure the reaction starting before the concentration of permanganate was so high as to cause excessive temperatures and foaming when the reaction finally started. The precipitate was washed by decantation, which with a 230 kg. lot in a 38-cu. meter tank required 8 to 9 washings.

*Preparation of Copper Oxide.*—Ninety-five g. of copper sulfate pentahydrate is dissolved in 200 cc. of hot water and heated to the boiling point. Thirty-four g. (actual total alkalinity) of sodium hydroxide is used in the form of a lye of about 1.35 sp. gr. The hot copper sulfate solution is added to the alkali with agitation and uncontrolled increase in temperature, the final temperature being usually 60 to 70°. After thorough stirring, the mixture is diluted to a suitable volume for washing and washed by decantation until the sulfates are practically all removed. Yield, about 30 g.

*Preparation of Cobaltic Oxide.*—Fifty-one g. of cobalt sulfate heptahydrate is dissolved in 200 cc. of cold water. This solution is added to 25 g. of sodium hydroxide as lye of about 1.35 sp. gr., and 8.6 g. of sodium hypochlorite (actual, by titration) is then added in the form of a 10% solution with constant agitation. After stirring for about 5 minutes the mixture is diluted and washed until practically free from chlorides. Yield, about 15 g.

*Mixing, and Precipitation of Silver Oxide.*—After thorough washing, the manganese dioxide, copper oxide and cobaltic oxide are mixed and the silver oxide precipitated in the presence of the mixture. Two and a half g. of sodium hydroxide (free from chlorides) is dissolved in a small quantity of water and added to the suspension, and then 7.4 g. of silver nitrate dissolved in about 50 cc. of water, is added with thorough agitation. The silver nitrate is equivalent to about 5 g. of  $\text{Ag}_2\text{O}$ . After the mixed precipitate is washed practically free from dissolved salts, the subsequent treatment is essentially the same as that of the 2-component mixture, which will be described below.

*Preparation of the Two-component Mixture.*—The manganese dioxide for use in the 2-component mixture is prepared in the same way as that used in the 4-component mixture. The copper is precipitated as the basic carbonate rather than the hydrated oxide and the precipitation is preferably carried out in the presence of the precipitated and partially washed manganese dioxide.

*Preparation of Basic Copper Carbonate.*—Ninety-five g. of copper sulfate pentahydrate and 55 g. of anhydrous sodium carbonate are each dissolved in 200 cc. of hot water, the soda solution added to the suspension of manganese dioxide and the copper sulfate solution added to the mixture

with thorough agitation. After a few minutes the mixture is diluted and washed by decantation until practically free from sulfates. The copper sulfate is equivalent to about 30 g. of  $\text{CuO}$ .

**Filtration and Drying of the Precipitates.**—In the case of either mixture the washing is completed, wet-ground fines added if desired and the precipitate filtered in a filter press or on a Büchner funnel. The cake is kneaded, on the large scale mechanically for about 8 minutes, and submitted to a pressure of 4000 to 6000 lbs. per sq. in. between felt pads or camels'-hair cloths to permit the escape of the water. The cakes are dried at about  $50^\circ$ , crushed, screened and the granules redried for 4 hours at  $200^\circ$ , and preserved in sealed containers.

### The Variation of the Activity of the Catalysts with the Method of Precipitation of the Oxides.

Since the oxides prepared by high temperature reactions, as by oxidation of metals or ignition of nitrates, were found to have a much lower activity at ordinary temperatures than those prepared by precipitation, the latter methods of preparation were those most extensively studied. It was found to be desirable in all cases to carry out the precipitations in such a way as to obtain a very finely divided precipitate; thus in precipitating metallic hydroxides concentrated solutions of the reagents were used. Reasonably complete washing is very essential, probably because of the tendency of the soluble salts to collect at the surface of the lumps by capillarity and so decrease the available surface. Of course, in the case of mixtures containing silver oxide, chlorides are particularly undesirable as silver chloride is inert as an oxidation catalyst.

The manganese dioxide is the chief component of both mixtures and hence has a very considerable influence on the activity and hardness. The preparation of it in a finely divided form with a high oxygen content, that is, with a minimum content of lower oxides, is more complicated than that of the other oxides and wider variations in quality were observed. The activity of the various samples was ordinarily tested by making them up into one of the standard mixtures with the other oxides of known activity and testing the resulting mixture with carbon monoxide at room temperature. In some cases, however, they were tested alone in an apparatus in which the temperature of the granules and gas stream could be raised and the temperature determined at which the sample oxidized a carbon monoxide—air mixture with a definite efficiency.

The oxidation of manganese sulfate suspended in sulfuric acid was the method investigated in most detail, since it appeared to lend itself best to large-scale operation, although other methods were tried with more or less success. The simple decomposition of potassium permanganate in conc. sulfuric acid gives a very active product but this procedure is not entirely unattended by risk, for dust particles or other organic matter are oxidized rather violently by the permanganic acid with evolution of

clouds of brown fumes. The product obtained by this reaction is usually darker brown than by the standard method and in the 2-component mixture it dries to a harder granule which is a little more active at low temperatures. The reduction of potassium permanganate in neutral solution by organic compounds such as methyl alcohol gives a fairly active product but at a higher cost than a process obtaining part of the manganese from manganous salts. Processes involving the oxidation of manganous sulfate by potassium permanganate in aqueous solution were uniformly unsatisfactory, the resulting material being soft and practically inactive. This is probably due to the formation of lower oxides and manganites rather than a manganese dioxide free from alkali salts.

In the standard method the reaction is complicated by the decomposition of part of the permanganic acid with evolution of oxygen. The manganese dioxide is not all present as such in the acid mixture but some is present as manganese disulfate,  $\text{Mn}(\text{SO}_4)_2$ , which is hydrolyzed on pouring into water. The material prepared by this method is actually a mixture of oxides and the analysis corresponds with about  $\text{MnO}_{1.85}$ . To a certain extent the available oxygen content is a measure of the activity, but the physical state must also be considered. Since the manganous sulfate is largely suspended in the acid rather than dissolved, it must be finely ground, as otherwise its utilization is very incomplete, only the outside of the particles being oxidized. But the utilization is never entirely complete and the reaction should therefore be carried far enough in the acid mixture to use practically all of the permanganate, to prevent the remainder from reacting on dilution to produce oxides of manganese which are soft and inactive and which seem to have some tendency to coat over and spoil otherwise good material. In the choice of the temperature for the reaction, variations in activity, hardness and yield must be considered. At high temperatures the decomposition of the permanganic acid takes precedence over the oxidation reaction with the consequence that the utilization of the manganese sulfate is very poor, and at temperatures above about  $85^\circ$  the available oxygen content of the product begins to fall off with corresponding decrease in activity. At temperatures below about  $55^\circ$  it is difficult to obtain a complete utilization of the permanganate and the product is generally very soft. The temperatures called for in the directions are those which experimentation has indicated are most suitable for preparing a hard active product. The low temperature at the beginning permits the building up of a high concentration of permanganic acid, and by proper temperature control this is kept in considerable excess throughout the course of the reaction. This is the condition which tends towards the formation of large amounts of manganese disulfate and higher oxides and reduces the formation of lower oxides to a minimum. After the permanganate is all added, the temperature is held at about  $60^\circ$

until the permanganate is practically all used up, which usually requires 10 to 15 minutes. Too long a time is to be avoided as there is a tendency for the manganese sulfate on the inside of the lumps to react with the higher oxides or manganese disulfate giving lower oxides on dilution. A reaction of this type is shown by the mixture becoming thick and granular on standing and the color changing from a dark brown to a dirty purple. The method of dilution is quite important as it has a great effect on the hardness of the resulting material. In order to obtain a high degree of dispersion of the precipitate, the hydrolysis of the manganese disulfate should take place rapidly. This is accomplished by having the acid mixture enter a large amount of water in fine streams and with adequate stirring.

The methods of precipitation of copper oxide were studied largely in connection with the preparation of an absorbent for arsine although in the later work on carbon monoxide the copper oxide samples were tested by making them up into mixtures as in the case of the other oxides. More care is necessary to prepare a copper oxide that will oxidize arsine completely at room temperature than is necessary in preparing copper oxide for use in the 4-component mixture, due probably to the fact that the physical texture of the mixture is largely a composite of that of the components while with a single oxide such equalizing factors are absent. The method used in the preparation was to mix rather concentrated solutions of sodium hydroxide and copper sulfate, boil for various lengths of time, and dilute, wash and filter. In general it was found that the samples of copper oxide most active as oxidizing agents for arsine were those consisting of a rather soft porous granule. The hardness could be controlled by the conditions of acidity or alkalinity at the end of the precipitation. A precipitation with considerable excess alkali gave a precipitate which was slow in settling and hard to filter, and which dried down to a hard dense, black mass with low activity. The sodium hydroxide used contained about 4% of sodium carbonate and with insufficient amounts of alkali, carbon dioxide was evolved as the last of the copper sulfate solution was added. Under these conditions the precipitate was brownish-black with a green tinge. Such samples were active but rather soft for a satisfactory granule. The optimum conditions for an active yet fairly firm granule were found between these two extremes. By carefully controlling the amount of sodium hydroxide or by using an excess and then partially neutralizing with sulfuric acid, these conditions were realized. The correspondence between physical properties and the alkalinity of the solution is that which would be expected from the tendency of the precipitate to coagulate in acid solution and redisperse in alkaline. The low activity of the samples prepared with a large excess of alkali is probably to be attributed to a reduced porosity in the very dense granules. The catalytic oxidation of arsine affords a good example of the action of promoters, for it was

found that soaking the granules in a solution of  $\frac{1}{2}$  % of their weight of silver nitrate and drying materially increased the activity of poor samples. The life of catalysts for the oxidation of arsine at low temperatures is of course limited by the deposition of metallic arsenic or oxides.

Since the hardness of the copper oxide was more readily controlled than that of the manganese dioxide, it was usual, in order to obtain the maximum hardness of the 4-component mixture consistent with high activity, to prepare a harder copper oxide than if it were to be used alone. For this reason an excess of alkali was used and the partial neutralization omitted in the standard procedure for preparing the 4-component mixture.

The precipitation of basic copper carbonate by the addition of copper sulfate solution to sodium carbonate solution results in a material which is very soft when dried and partially converted into the oxide by heating. Judging from the activity of basic copper salts in the oxidation of arsine, it was thought that an increased activity might be obtained on substituting such basic copper carbonates for the ordinary hydrated copper oxide in the 4-component mixture, but this desired effect was not realized in the experiments performed. This was probably due to the formation of silver carbonate in place of part of the silver oxide, since some preliminary experiments indicated that silver carbonate is less active than silver oxide. That the basic copper carbonate is more active than the oxide, at least in mixtures, is indicated by the fact that the 2-component mixture made up with the latter has only a slight activity in comparison with the standard 2-component mixture. This latter mixture tends to give an excessively soft granule, but this can be overcome by pressure.

The experiments of Wright and Luff had shown that cobaltic oxide is remarkably active in the oxidation of carbon monoxide at low temperatures. Hüttner<sup>10</sup> and others had shown that cobalt oxide, prepared under certain conditions, contains more oxygen than corresponds to the formula  $\text{Co}_2\text{O}_3$ , due to the presence in the mixture of a cobalt peroxide or dioxide. It was thought that such cobalt oxide mixtures would probably be more active than those of lower oxygen content, and this was found to be the case, properly prepared samples oxidizing carbon monoxide—air mixtures catalytically at room temperatures. Hüttner used sodium hypochlorite or alkaline solutions of iodine, and in the latter case obtained a higher ratio of oxygen to cobalt. Preliminary experiments did not indicate any advantage in the use of iodine, and most of the samples were made using hypochlorite as the oxidizing agent.

Because of the effect of cobalt oxide on hypochlorite solutions, catalyzing their decomposition with evolution of oxygen, it is necessary to use an excess of 25 to 50 % of hypochlorite to obtain a high ratio of oxygen to cobalt. The effect of temperature of precipitation on the oxygen content

<sup>10</sup> Hüttner, *Z. anorg. Chem.*, **27**, 81 (1901).

of the precipitate is slight provided sufficient hypochlorite is used to offset the more rapid decomposition at the higher temperatures. When a sufficient excess of hypochlorite and of hydroxide was used and the precipitate thoroughly washed no difficulty was experienced in obtaining a comparatively soft, porous, active granule; in fact, the samples were frequently so soft as to be difficult to handle in the tests. The only samples which were hard and lacking in activity were those prepared with insufficient hypochlorite, and the poor activity of these samples was probably due rather to the low oxygen content than to the low adsorptive properties.

While in many cases the activity of a mixture of catalysts is merely a composite of the activities of the several components, it has often been found that mixtures of catalysts are more active than any of their components. The complete explanation of this co-activation of catalysts is still lacking, but the results of the present investigation indicate that the chemical nature of the components and the physical properties of the mixture are very important factors. The use of mixed catalysts was found to be quite essential in obtaining the requisite activity towards carbon monoxide at low temperatures. Of the common oxides tried, none acted alone as an active catalyst with the exception of cobaltic oxide. The latter, however, is itself a mixture of oxides, since, as prepared, the ratio of oxygen to cobalt is about 1.6:1.

A comparison of the activity of the 2-component mixture and its components is given in Table I. The tests were made with a 1% carbon monoxide—air mixture at a space velocity of 6000 cc. of mixture per hour per cc. of catalyst. The oxides were prepared under suitable conditions for obtaining active catalysts and were in the form of 8- to 14-mesh granules in a layer 5 cm. deep as previously described. The temperatures given are those of the entering gas, and the exterior of the catalyst tube was maintained at practically the same temperature. The efficiencies are the percentages of gas oxidized after the conditions became constant.

TABLE I.

Comparison of the activities of the 2-component mixture with Those of Some Single Oxides.

Oxide.	Dry Gas.		Humidity 14mm.	
	Temperature. ° C.	Efficiency. %.	Temperature. ° C.	Efficiency. %.
CuO	102	97	102	18
MnO <sub>2</sub>	100	96	100	17
Co <sub>2</sub> O <sub>3</sub>	0	100	78	100
Fe <sub>2</sub> O <sub>3</sub>	100	40	...	...
MnO <sub>2</sub> + CuO	-10	100	76	100

The last two columns illustrate the characteristic effect of humidity which will be discussed later. The increased activity of the 2-component mixture over the activity of the copper oxide and manganese dioxide

alone is very marked. The co-activation is seen to have lowered, by more than  $100^{\circ}$ , the temperature required in the case of dry gas for 100 % efficiency. As has been stated, the 2- and 4-component mixtures were the most satisfactory from the standpoint both of activity and cost, but, of the large number of mixtures prepared, there were a few others that were fairly active. It was found that manganese dioxide and silver oxide gave an active catalyst, but not materially better than the standard 2-component mixture. A 3-component mixture consisting of 50 % manganese dioxide, 30 % cupric oxide and 20 % cobaltic oxide was found to be active towards dry carbon monoxide—air mixtures but it had much less tolerance towards humidity than the standard 4-component mixture. Some samples of nickelic oxide were prepared in the same way as the cobaltic oxide and substituted for the latter in the 4-component mixture. These mixtures did not operate catalytically towards dry gas for an indefinite length of time at room temperature. The oxidation of the carbon monoxide was accompanied by gradual reduction of the catalyst and loss of activity unless the temperature was slightly elevated. Ferric oxide was found to be even less active than nickelic oxide in these mixtures.

#### The Effect of Kneading and Pressure upon the Activity and Hardness of the Catalysts.

After the oxides are precipitated, washed and mixed, or preferably in many cases precipitated in the presence of each other, subsequent treatment, with the exception of drying, has more effect on the hardness than on the activity. In cases where the catalyst is used under unfavorable conditions, for instance, with some moisture in the gas—air mixture or at low temperatures (as at  $-15^{\circ}$ ), the oxidation of the carbon monoxide takes place to a greater or less extent at the expense of the available oxygen of the catalyst itself, and is terminated by the exhaustion of the catalyst. The life of a given volume of the catalyst under these conditions is dependent, of course, upon the amount of available oxygen present, which in turn is dependent upon the density. A high density also is advantageous in that the heat of the reaction tends to give a higher temperature within the denser granules which favors the re-oxidation of the reduced catalyst and hinders the adsorption of moisture.

The effect of kneading and high-pressure filtration upon the hardness and density of the catalysts was studied in some detail because of its importance in the utilization of fines and in preparing a satisfactory granule from the 2-component mixture. Even after filtering the mixed precipitates at a pressure of 7 kg. per sq. cm. (100 lb. per sq. in.) and blowing the excess water out of the cake by compressed air, the moisture content of the material is still about 60 %, although part of this is water of hydration of the oxides. It was found that kneading broke up the structure of the

cake so that the mass became much more fluid, and additional water could be pressed out at the same pressure if desired. Even without the second pressing, the mass on drying had a greater density and hardness, if the kneading was not excessive. This is doubtless due to a breaking down of the lamellar structure of the cake as it is formed in the filter press, permitting a closer packing of the particles. The data obtained in one series of kneading experiments are presented in Table II. A considerable amount of cake was kneaded in a Werner and Pfleiderer kneading machine and small samples removed at the times indicated. Unfortunately the hardness was not determined in this series but it was found that in general the increase in hardness was somewhat less than the increase in apparent density and the maximum was reached sooner. With the type of kneading machine used, the maximum hardness was usually reached in 6 minutes and the maximum density in 9.

TABLE II.  
Effect of Kneading.

Time of kneading. Min.	Apparent density.	Volume activity.	Weight activity.
0	0.57	32	56
1	0.59	37	63
3	0.64	53	83
5	0.66	55	83
7	0.72	65	90
9	0.75	67	89
11	0.72	64	88
14	0.67	54	81

The column headed "Volume activity" gives the number of minutes that the given volume of sample operated above 85 % efficiency on 1 % carbon monoxide—air containing 14 mm. of water vapor. The "Weight activity" is the volume activity divided by the apparent density, these values of course being only relative. All of these samples were catalytic for an indefinite time on dry gas. The effect of kneading on activity is largely indirect, in that the increased density permits the reaction to go on for a longer time when it is taking place at the expense of the oxygen of the catalyst itself. The occurrence of maxima in the apparent density and hardness curves is probably due to the inclusion of air bubbles in the more thoroughly kneaded samples. The fact that hand kneading gave uniformly better results than machine kneading points towards the same conclusion, for in hand kneading there is less opportunity for the inclusion of air, although the superiority of hand kneading may be due in part to the packing or settling action in comparison with the rubbing action of machine kneading.

The experimentation with regard to hydraulic pressing was concerned chiefly with the utilization of fines, as with the 4-component mixture

it is possible to prepare a reasonably firm granule without the use of hydraulic pressure, except when fines are added. With the 2-component mixture, however, hydraulic pressure is necessary in order to prepare a granule of satisfactory hardness. In order to utilize the fines formed in the crushing operation, they were ground wet in a ball mill to a fine slime and added to the original precipitate and the mixture filtered. If this cake were dried immediately the product would be much too soft for use in gas masks, but by subjecting the cake, after kneading, to high pressure between felt pads to permit the escape of the water, a product is obtained of hardness similar to that of the original material or better. The density is usually somewhat higher and the activity at least as good. The action of high pressure is largely to reduce shrinkage in drying to a minimum and so eliminate shrinkage cracks as far as possible. The results of a typical series of experiments with the 2-component mixture and varying proportions of wet ball-milled fines are presented in Table III. The material was all from a single set of precipitations. The cakes were kneaded for 7 minutes and pressed between felt pads, the pressure being raised gradually and held at the final value for about 5 minutes to permit the escape of the water. At the higher pressures the cake was reduced in thickness from 25 mm. to about 10 mm.

TABLE III.  
Effect of High-pressure Filtration.

Fines. %.	Pressure. lbs./sq. in.	Hardness. %.	Apparent density.	Volume activity.	Weight activity.
50	80	20	0.55	32	58
50	1000	56	0.60	52	87
50	2000	60	0.62	50	81
50	4000	56	0.68	53	78
40	80	27	0.57	48	84
40	1000	76	0.61	52	85
40	2000	65	0.64	53	83
40	4000	78	0.69	53	80
40	6000	90	0.72	63	87
30	80	32	0.56	35	63
30	1000	64	0.62	50	81
30	2000	62	0.65	54	83
30	4000	62	0.69	55	80
30	6000	62	0.73	66	80

These figures show that the apparent density and volume activity increase quite regularly with the pressure applied to the cake. The hardness figures do not show so much regularity, but this is largely due to inherent errors in the hardness determination, which are particularly evident in this series because the method had not yet been thoroughly standardized. A hardness of 70 on this scale may be interpreted as quite

sufficient for gas-mask use. It is evident that the apparent density is not a satisfactory criterion of hardness when the mixtures contain fines. The content of fines may be increased above 50 %, in fact the use of wet ball-milled fines alone gave fairly satisfactory results, when thoroughly kneaded and pressed at high pressure.

The discussion of the effect of the degree of drying on the activity of the catalysts will be postponed until after the effect of the humidity of the gas mixture has been considered.

### **The Effect of the Conditions of Operation on the Activity of the Catalysts.**

Under the conditions of operation used in the standard tube-tests with dry carbon monoxide—air mixtures at room temperature, that is, using a 5 cm. layer of 8- to 14-mesh granules and a rate of flow of 500 cc. of 1% gas per sq. cm. per minute, good samples of either the 2- or the 4-component mixture operate at efficiencies closely approaching 100 % for an indefinite length of time. Such samples also operate at high efficiency on more dilute mixtures as shown by tests with concentrations of 0.1% or less. The theoretical temperature rise under adiabatic conditions due to the heat of the reaction is about 100° for a 1% mixture. Because of this heat effect, little difficulty is experienced in obtaining a complete oxidation at higher concentrations even with rather poor samples, although with concentrations much above 5 % the temperature rise may be sufficient to impair the activity of the catalyst after cooling. With very high concentrations the catalyst may even sinter together and be entirely inactive when cold.

The activity of the catalysts at low temperatures is of course very important when they are to be used in gas masks in exposed locations. The effect of the temperature of the carbon monoxide—air mixture on the activity is masked somewhat by the heat of the reaction, but it can be determined readily by using dilute gas mixtures so that the heat effect is small. In general for each particular sample of catalyst and gas concentration there is a minimum temperature at which the catalyst operates catalytically at 100 % efficiency. Below this temperature the efficiency gradually falls off to a more or less constant value for each temperature but returns again to 100 % when the temperature is raised. Most of the tests were made with 0.5 % carbon monoxide and the catalyst was placed in a glass tube surrounded by a freezing mixture so that there was little opportunity for it to heat up by the heat of the reaction. It was found that the 2-component mixture operated better at low temperatures than the 4-component mixture although individual samples varied somewhat, especially when there were variations in the methods of pressing and drying. The samples prepared with high pressure were much better than those

filtered at comparatively low pressures and adequate drying was found to be quite essential. A typical sample of the 2-component mixture, when tested with 1% carbon monoxide at  $-15^{\circ}$ , operated initially at high efficiency, but after a few minutes the efficiency began to fall and gradually decreased to about 35 % where it remained in apparent equilibrium. When the temperature of the gas and catalyst tube was allowed to rise to  $0^{\circ}$ , the efficiency gradually rose to 100 %. Similar experiments on manganese dioxide and copper oxide alone at higher temperatures indicated that under proper conditions this phenomenon is accompanied by reversible reduction of the catalyst, that is, the catalyst is partially reduced at the lower temperature and reoxidized at the higher. This reduction is different from that obtained by treating the catalyst at a high temperature with carbon monoxide or other reducing agents in the absence of an excess of oxygen for in this case the reduction is more complete and is usually accompanied by a change in structure. The activity cannot then be restored by re-oxidation with air.

The general effect of water vapor in the gas mixture is to diminish the activity of the catalysts so that higher temperatures are necessary for definite efficiencies than when operating with dry gas. Somewhat the same effect is brought about by a diminution of the oxygen content of the gas. While, in gas-mask use, the oxygen requirements of the man are so high that such effects do not enter under any conditions under which a man could live, they are of importance in connection with the application of the catalysts to the removal of carbon monoxide from hydrogen by preferential combustion and in other industrial applications. It was found that for an equilibrium efficiency of 100 % with 28 mm. of water vapor, reducing the oxygen content of the gas to as low as 100 % excess of that theoretically required for the combustion only necessitated an increase of temperature of about  $10^{\circ}$  over the temperature required with a carbon monoxide—air mixture containing the full oxygen content. It was also found that when operating with the 2-component mixture on a mixture containing 0.5 % carbon monoxide, 0.5 % oxygen and 55 mm. of water vapor at a space velocity of 6000 cc. of gas per cc. of catalyst per hour, 190 hours of continuous operation at  $102^{\circ}$  and an average efficiency of 93 % did not result in any appreciable deterioration of the catalyst.

The humidity of the carbon monoxide—air mixture has a very marked effect on the activities of the various oxides and mixtures. The effect is best described as reversible poisoning, to distinguish it from the type of poisoning brought about by sulfur compounds and some of the war gases. While the 2-component and 4-component mixtures act catalytically for an indefinite length of time on dry gas mixtures at ordinary temperatures, with 1% gas mixtures half saturated with water vapor at room tempera-

ture the activity falls to 85% in about an hour and rapidly decreases from then on. If the mixture is changed from wet to dry at any time before the catalyst has stopped acting, the efficiency gradually returns to the original value of about 100% in the case of active samples. The rate at which the efficiency of the catalyst decreases is a function of the temperature at which the test is made and hence indirectly of the concentration of the gas, since the heat of the reaction raises the temperature of the catalyst. At temperatures somewhat above room temperature, the catalytic oxidation proceeds indefinitely even with gas mixtures of high humidity.

Fig. 1.

At intermediate temperatures and humidities, the activity does not fall to zero but only to a fairly definite value for any particular sample of catalyst. These efficiencies are approximately the same when approached from either side if sufficient time is allowed for conditions to become constant. The variation of these equilibrium efficiencies with the temperature is shown by the data of Table IV, which have been plotted in Fig. 1. In obtaining these results the catalyst was placed in a copper tube immersed in a water-bath which was maintained at the desired temperature, and the gas was preheated by passing through another tube immersed in the bath. The bath was held at each temperature long enough for constant efficiency to be obtained. While these results are of interest from the standpoint of the mechanism of the reaction, the equilibrium efficiencies at ordinary temperatures are so low for the usual humidity that the time necessary for the efficiency of the dried catalyst to fall to a definite value is of greater importance in connection with the application

of the catalysts to gas masks. It was found that this time was materially shorter at low concentrations where the heat effect of the reaction was small. This is shown in another way by the data of Table V, which represents the results of a series of experiments in which air at room temperature containing 4 mm. of water vapor was passed through a 5 cm. layer of the 2-component mixture at the rate of 500 cc. per sq. cm. per minute for a definite length of time and followed by 1% carbon monoxide also containing 4 mm. of water vapor.

TABLE V.

Time of humidification. (Min. of air flow.)	Life to 85% efficiency. (Min. of gas flow.)
0	236
30	128
45	74
60	4

Other experiments have shown that, when air of 4 mm. humidity is passed over the catalyst dried in the usual way, the moisture in the air is absorbed practically completely during the first hour. These results indicate that an absorption of water equivalent to about 3.6% of the weight of the catalyst is sufficient to reduce the efficiency to 85%. It is evident, therefore, that the dryer used in the canister must be quite effective in order to protect the catalyst from moisture.

The tests referred to hitherto were all made with the standard rate of flow of 500 cc. per sq. cm. of cross section per minute and with a depth of layer of 5 cm., that is, with a space velocity of 6000 cc. of gas per cc. of catalyst per hour. In the design of gas-mask canisters it is desirable to

reduce the resistance to the minimum consistent with efficient operation of the catalyst. The resistance is of course dependent upon the size of the granules and the area and depth of layer. As the size of granules is increased and the depth of layer decreased, there evidently must come a time when the oxidation is incomplete because the molecules of carbon monoxide do not all have an opportunity to come into contact with the catalyst. Since this effect is not due to insufficient activity of the catalyst itself, it is referred to as mechanical leakage. In order to determine approximately the conditions under which mechanical leakage begins to be appreciable, a series of experiments was performed with a constant space velocity of 7800 but with varying size of granules and depth of layer. The results of these experiments are presented in Table VI. The equilibrium efficiencies were rapidly attained and remained constant except for slight fluctuations. No mechanical leakage was encountered at this space velocity with layers 2 cm. or more thick and 10 to 14 mesh or finer.

TABLE VI.

Efficiencies with Various Sizes of Granules and Depths of Layer.

	Depth, cm. Rate of flow, cc. / sq. cm. / min.	2. 260.	1.5. 195.	1. 130.
Mesh, 10-14 .....		100%	99.0%	96.5%
Mesh, 14-20 .....		100	99.8	<del>98.7</del>
Mesh, 20-28 .....		100	100	99.5
Mesh, 28-35 .....		100	100	99.8

The pressure drop at these rates of flow varied from 12 mm. of water for a 5cm. layer to about 0.2 mm. for a 1cm. layer of 10- to 14-mesh material. It is evident from these figures that the use of the catalyst in the form of granules gives a very satisfactory contact with the gas without at the same time introducing an excessive resistance to the flow.

The high degree of porosity of the catalysts and their consequent high absorptive power for many volatile substances has been mentioned. Many of these substances, particularly sulfur and halogen compounds, act as poisons and tend to prevent the catalytic oxidation of carbon monoxide. It might be thought that the sensitiveness of the catalysts to poisons would seriously interfere with their practical use in gas masks, but such is not the case for the catalyst may be protected readily from large concentrations of poisons by a layer of activated charcoal in the canister, while with small concentrations the poisoning is progressive, the first layers of the catalyst absorbing practically all of the poison leaving the rest of the catalyst available for the oxidation reaction.

#### The Effect of the Degree of Drying on the Activity of the Catalysts.

The usual method of drying was that indicated by preliminary experiments to give satisfactory results, namely drying the filter cake at about 120°, crushing to size and redrying at 200° for about 4 hours. Additional

experiments were made to test the effects of drying *in vacuo* or at higher temperatures. A fairly large sample of 2-component cake after hydraulic pressing was ground and bottled after thorough mixing to insure a uniform distribution of grains of slightly different moisture content. The loss of weight on drying was determined and the dried samples were tested with 1% carbon monoxide—air mixture containing 14 mm. of water vapor. The results are given in Table VII.

TABLE VII.  
Effect of Degree of Drying.  
Conditions of Drying.

Expt.	Temp. °C.	Time. Hrs.	Pressure. Mm.	Loss in weight, %.	Life to 85% efficiency, Min.
16	100	3	12	37.0	41
17	400	5	12	47.3	51
20	{ 120	15	Atm. }	39.9	52
	{ 200	5	Atm. }		

The catalyst dried as in Expt. 17 did not lose more than 0.1% of water when heated to redness in a current of air in a quartz tube, and this small amount was probably absorbed from the air while the material was being placed in the tube. Analysis indicated that drying at 400° entailed a loss of available oxygen of 0.6% on the original wet weight. Allowing for this, the moisture content of the material after drying as in Expt. 20 is about 11.5%. Other experiments have shown that the moisture content may be as high as 14% without seriously decreasing the life of the catalyst on moist gas, and this is not increased much by more complete drying. These results are interesting in connection with the data of Table V, which showed that the moisture absorbed during the test with gas containing 4 mm. of water vapor was only about 3.6%, which is only a fraction of the water removed on complete drying, yet the completely dried samples have approximately the same life with moist gas as the incompletely dried ones. This indicates that the moisture absorbed from the gas remains for the most part as a film on the surface of the catalyst, hindering the adsorption of the gas molecules and oxygen molecules, and does not re-hydrate the oxides to any considerable extent.

The properties of the 4-component mixture proved to be somewhat different, in that a sample after the usual drying at 200° contained only 4.5% of residual water. Tests with 1% gas containing 14 mm. of water vapor gave a life of 58 minutes to 85% efficiency for the sample after standard drying, but a life of only 25 minutes after complete dehydration at 400° and 12 mm. This is probably due to partial decomposition of the silver oxide under these conditions.

### Application of the Catalysts.

While in the foregoing the activity of the catalysts has been discussed principally in connection with the oxidation of carbon monoxide, it has

been found that these catalysts are able to reduce materially the temperature required for the oxidation of a variety of gaseous reducing agents by atmospheric oxygen. For continued catalytic action it is necessary, however, that neither the reagents nor the products should poison the catalysts and that the temperature of operation should not be so high as to cause injury to the catalysts by sintering or loss of oxygen. Because of the possible industrial applications, some attempts were made to apply the catalysts to organic oxidations in the vapor phase, such as toluene to benzaldehyde and naphthalene to phthalic anhydride. It was found that with the 2-component mixture, the oxidations started at the comparatively low temperatures of 170° and 220° respectively, but that it was very difficult to prevent the reaction from going too far with the formation of carbon dioxide and water as the principal products. This was due largely to the difficulties inherent in controlling the temperature of operation. The heat evolved in such organic oxidations, particularly when the reaction goes to completion, is very considerable in amount and the proper dissipation of it is a serious problem. The factors such as high porosity and fineness of particles which give the catalysts their high activity are also the ones which render them poor conductors of heat and this makes temperature control by cooling the walls of the catalyst chamber very unsatisfactory. Since other methods of temperature control are inconvenient, it seems probable that the catalysts would have to be considerably modified in order to make them suitable for organic oxidations.

### Summary.

A description is given of some active catalysts developed by the Chemical Warfare Service for use in gas-mask canisters as a protection against carbon monoxide. These catalysts are mixtures of metallic oxides, the two most satisfactory mixtures containing manganese dioxide and basic copper carbonate, and manganese dioxide, copper oxide, cobaltic oxide and silver oxide respectively. These mixtures oxidize carbon monoxide rapidly and completely at ordinary temperatures, and, when protected by a drying agent such as calcium chloride, are suitable for use in gas masks against the concentrations of carbon monoxide ordinarily met with except under conditions where an oxygen helmet is necessary because of the reduced oxygen content of the air. The factors influencing activity, such as the constituents of the mixtures, the conditions of precipitation, the mechanical treatment of the precipitate and the method of drying, are discussed and a description is given of the performance of the mixtures under various conditions of operation.

**THE DETERMINATION OF THORIUM IN MONAZITE SAND  
BY AN EMANATION METHOD.**

BY HOMER H. HELMICK.

Received March 21, 1921.

**Historical.**

In a recent paper,<sup>1</sup> Cartledge described an "emanation method" for the determination of thorium in monazite sand which was based on the facts: (1) thorium is the first member of the series of radioactive elements now known as the Thorium Series; (2) one of the members of the series, thorium emanation, is a gas. As a further basis for his method, he assumed: (1) on account of the great age of monazite, the elements of the thorium series have reached "radioactive equilibrium," (2) in an acid solution of monazite sand, the emanation is in such a condition of availability that it can be practically completely swept out by bubbling air through the cold solution. In our work on this problem, we have accepted the same facts and made the same assumptions.

Cartledge states that his method "by a triplicate analysis will give the thorium content within 1.5 % of its true value," and pointed out that the inability of the method to give results of a higher degree of accuracy was probably due to the adsorption of thorium X by the undissolved material in the final solution, by the filter paper employed in the process of making the solution, and on the walls of the vessels used. Assuming that he was correct as to the sources of error, it was obvious that a much greater degree of accuracy could be obtained if a method could be perfected which would produce a complete solution of the sand without filtration and which would require the use of but one vessel. A thorough study of this problem led to a very satisfactory solution.

**Proposed Method and Apparatus.**

The method developed in this paper involves the following experimental steps: (1) preparation of the sample, (2) fusion, (3) solution of the melt, (4) transfer to solution vessel, (5) measurement of the ionization due to the sample. The preliminary investigation of each step will be recounted in order.

(a) **Preparation of the Sample.**—No difficulty was experienced in connection with this step, the same method being used throughout the experiments and in the final method. The sample was simply weighed out from a quantity of well-mixed, finely divided and dried monazite sand. Details are given under the description of the final method in the latter part of this paper.

<sup>1</sup> Cartledge, *THIS JOURNAL*, 41, 40 (1919).

(b) **Fusion.**—It occurred to us that a fusion of monazite sand with a suitable flux might prove a satisfactory substitute for the acidified water solution used by Cartledge, inasmuch as a fusion would eliminate loss of thorium X through filtrations and use of several vessels. Fusions were therefore made of monazite sand with (1) potassium hydrogen sulfate, (2) equal parts sodium carbonate and potassium carbonate, (3) anhydrous metaphosphoric acid. We were unable to sweep any emanation out of the potassium hydrogen sulfate melt, so it was eliminated from further consideration. The alkali carbonate melt was also abandoned because of the considerable percentage of sand remaining undecomposed, the violent effervescence, and the high temperature necessary. The fusion with anhydrous metaphosphoric acid appeared most promising, proceeding fairly quietly at about  $700^{\circ}$ , giving a melt only moderately viscous and leaving very little material undecomposed. Many experiments in our later work showed that this small amount of undecomposed material, chiefly silica and ilmenite, was the probable cause of disturbing effects on account of adsorption of thorium X. This difficulty was overcome by the addition of potassium hydrogen fluoride and metaphosphoric acid during the fusion in such a way that hydrogen fluoride was produced in the fused mass at a high temperature as well as practically continuously for some time, these conditions being found necessary for the removal of the objectionable compounds of silicon and titanium in the form of volatile fluorides. The detailed procedure is given in the latter part of this paper.

(c) **Solution of the Product of the Fusion.**—Our original plan had been to sweep the emanation directly out of the fused mass by bubbling air through it; but we were unable to find a vessel which would be inexpensive and at the same time both withstand the action of the hot fused material and resist deformation by pressure necessary to force air through the fused mass. It seemed that a platinum vessel would be necessary; but at this point a consideration of the chemical nature of monazite sand and the appearance of the cold metaphosphoric acid melt prompted us to attempt to dissolve it in water. This was found possible but extremely slow. To speed up solution a solvent was needed which had a high boiling point. Ordinary orthophosphoric acid immediately suggested itself, and experiment showed that our fusion of monazite sand could be fairly rapidly dissolved in 80 % orthophosphoric acid at  $240\text{--}250^{\circ}$  in a platinum crucible, the product consisting of a slightly viscous liquid, easily poured, and the crucible being readily washed out clean with water. Subsequent addition of a small amount of water with stirring produced a practically complete solution. Thus, by fusing monazite sand with metaphosphoric acid and potassium hydrogen fluoride in a platinum crucible, then heating and stirring the resultant mass with 80 % orthophosphoric acid, and finally

adding water, we achieved our original goal of a complete solution (without filtration) in a single vessel. It remained to be seen whether the emanation measurements would justify our expectations of increased accuracy.

(d) **Transfer to the Solution Vessel.**—It would have been ideal if the solution of monazite sand made in a single vessel, as outlined above, could have been left in that vessel during the emanation measurements. We found, however, that this was impracticable on account of the cost of a platinum vessel of the necessary size. We decided, therefore, to transfer the solution as finally produced in a platinum crucible of moderate size to a glass vessel specially designed for the emanation withdrawal. Results have shown that this can be done at a negligible sacrifice of accuracy. Throughout this paper this special glass vessel is called the "solution vessel," and is shown diagrammatically in Fig. 1. It is important that this vessel be made of good glass and have a thin bottom to enable the hot solution (which becomes viscous on cooling) to be poured in without danger; that it be tall and narrow to give maximum deëmanation by the stream of air bubbles; that it have ground-glass connections to prevent leakage and to insure constant length and volume of air line, as well as constant depth of air inlets below the surface of the solution; that it have a trap to prevent mechanical carriage of solution droplets into the ionization chamber; and that the bottom of the stopper be so high above the surface of the solution that only a negligible portion of the solution can be thrown against it by the bursting bubbles. Our experience also showed the most efficient air inlet jets to be those directed upward. The details of the technique used in transferring the hot solution from the platinum crucible to this glass vessel are given in the complete description of the method in the latter part of this paper.

Fig. 1.—Solution vessel ( $\frac{1}{2}$  actual dimensions).

(e) **Measuring Apparatus.**—We have used, with the changes and additions described below, the electroscope and accessories set up by Cartledge. A full description is given in his paper mentioned above, and we will therefore describe only the new parts.

**Insulation Protector.**—In the measuring apparatus as set up by Cartledge it was necessary to dry the stream of air after it had bubbled through the monazite solution before it entered the ionization chamber, in order to prevent the formation of a conducting film of moisture on the amber insulator separating the charged system from the grounded parts of the electroscope and ionization chamber. Cartledge dried the air stream

by means of a tube filled with granular calcium chloride. We examined the effects on the measurements of, respectively (1) this ordinary calcium chloride tube, (2) a much longer tube held horizontally with only the lower

Fig. 2.—Multiple condenser.

A—Air inlet; B—Air outlet; C—Water inlet; D—Water outlet.

half filled with granular calcium chloride, (3) a multiple condenser consisting of many short, small-bore condensers combined in parallel and cooled with running tap water (see Fig. 2), (4) an ordinary short condenser filled with glass beads. None of these driers was entirely satisfactory because of either formation of moist surfaces which apparently adsorbed some emanation, or changes in area of cross-section of air line on account of deposition of water in interstices between granules of drying agent or in interstices between beads, or in small tubes. Since it thus appeared extremely doubtful whether the air stream could be dried without undesirable effects, we abandoned all attempts to do so and directed our attention to direct protection of the insulation. An arrangement was accordingly devised whereby the insulator was directly protected by calcium chloride. The modification of the apparatus is shown in Fig. 3. The air gap between the rod R and the amber  $A_2$  constitutes a better resistance than amber itself. Circulation or diffusion of air through this gap must be slight, and whatever air does reach the amber insulator  $A_1$  is thoroughly dried by the calcium chloride in the wire-gauze basket B. Determinations made with this modification of the apparatus were much more satisfactory in every way than those made when the air was dried before entering the ionization chamber. There were, however, the following objectionable features: (1) the calcium chloride basket had to be taken out and refilled frequently, (2) the capacity of the electroscope seemed to change very slowly and very slightly during a determination, probably on account of the gradual wetting of part of the calcium chloride (mainly near the air gap), (3) uncontrollable and irregular effects due to minute quantities of emanation getting into the insulator chamber (in this article, by insulator chamber we mean the chamber fixed between the electroscope proper and the ionization chamber in this modification of the apparatus). In the apparatus which we have finally adopted, these

 chloride tube.

objectionable features are entirely eliminated by the use of the insulator protector shown in Fig. 4. Outside air is drawn, by the suction from the main "line," very slowly through calcium chloride solution S, thence through calcium chloride tube C, then through the insulator chamber, and finally out through the air gap. The insulator is thus kept constantly in an atmosphere of dry air. This protector functions perfectly, is extremely simple, and requires practically no attention.

Fig. 5.—Diagram of set-up for emanation measurements.

E—Electroscope; I—Ionization chamber; D—Drying tube; S—Solution vessel; M—Manometer; R—Pressure regulator.

*Pressure Regulator and Optimum Pressure Gradient.*—Our method depends on comparing the rate of discharge of an electroscopes by the emanation from a solution of the "unknown" sample with the rate produced by the emanation from a standard solution. In order that these rates may be directly comparable, it is necessary that the speed with which the emanation is drawn from solution to ionization chamber be the same,

within narrow limits, in both cases. Therefore a constant pressure gradient must be maintained along the suction line. This we have done

Fig. 6.—Pressure regulator.

by introducing a short branch from a point in the main line (farther from the solution than the ionization chamber) to a pressure regulator. Its relation to the rest of the setup is shown in Fig. 5. For a detailed drawing of the piece, see Fig. 6. Although the drawings show but 2 air inlets, the regulator actually used had 7, all admitting air under almost the same pressure conditions. The liquid used in the regulator is water, and adjustment to desired functioning pressure is attained by adding or subtracting water.

It is desirable, of course, to operate at that pressure at which the pressure coefficient of the rate of discharge of the electroscope is a minimum. A solution of monazite was therefore placed in the apparatus and the rate of discharge of the electroscope determined through the range of practical working pressures (our manometer readings). The results were plotted, the electroscopic readings being taken as ordinates and the pressure (manometer) readings as abscissas. The curve, Fig. 7, shows that the pressure coefficient of the rate of discharge of the electroscope is (for our apparatus) zero when the manometer reading is 11.5 cm. (of olive oil). (For the relation of the manometer to the remainder of the apparatus see Fig. 5.) By working at this pressure we therefore practically eliminated all error due to small pressure variations, attaining at the same time, as the curve shows, the extremely desirable effect of the maximum rate of discharge attainable. Thus, greater accuracy and maximum speed were attained.

#### Detailed Procedure.

**The Sample.**—About 50 g. of the well-mixed monazite sand is weighed out and ground to pass

Fig. 7.—Pressure-discharge curve.

through a sieve with 40 wires per cm. It is then thoroughly mixed, placed in a weighing bottle, and dried to constant weight at 115–120°. For a determination a 2.0g. sample is weighed out to within 0.001 g.

**The Fusion.**—The sample is well mixed, by pouring back and forth between sheets of glazed paper, with 5 g. of potassium hydrogen fluoride and 5 g. of anhydrous (recently fused) metaphosphoric acid. The mixture is placed in a 35cc. platinum crucible and brought slowly to the highest temperature of the Meker burner, and heated until no further reaction is apparent. With continued heating, 5 g. more of the metaphosphoric acid is added in small portions, the reaction being allowed to come to completion each time before another portion is added. After the last of the metaphosphoric acid has been added, the mass is allowed to cool, the crucible being rotated in such a way that, when cool, the material is distributed as evenly as possible over the surface of the lower half of the inside of the crucible. The cooled mass is practically transparent and is colorless, and glasslike.

**Solution of the Melt.**—After allowing the fused mass to cool, 20 cc. of 80 % orthophosphoric acid is added to the crucible, which is then placed in an air-bath where it is heated to 250–255° and maintained at that temperature for 3 hours. During that time it is stirred by a platinum wire stirrer attached to a motor. The liquid resulting from this treatment is, at 200–250°, about as viscous as light oil.

**Transfer to Solution Vessel.**—The solution vessel is suspended, to about  $\frac{1}{3}$  its depth, in a bath of conc. sulfuric acid at 190–200°. The stirrer is lifted just above the liquid in the crucible and rotated for a few seconds to free it of most of the liquid adhering to it. Then the liquid is quickly poured out of the crucible into the solution vessel. The latter is now taken out of the hot bath, placed on an asbestos board, and allowed to cool. Twenty cc. of water is run into the crucible, the liquid stirred vigorously for a minute or two and the washings poured into the cooled solution vessel. This operation is repeated with a second 20 cc. of water. Any heavy particles of undecomposed sand and occasionally a little ilmenite still remaining in the crucible are then washed into the solution vessel by using 5 cc. of water blown from a small wash-bottle holding just that amount. The mixture in the solution vessel is now rapidly stirred for at least 15 minutes. The same stirrer is used throughout the experiment. Finally the stirrer is lifted just above the liquid, rotated for a few seconds, and washed with 5 cc. of water from the small wash-bottle, the wash-water being caught in the solution vessel. Water is then carefully added to bring the volume of the solution up to 75 cc. as indicated by a line etched on the vessel. The stopper carrying the inlet tube is then fitted into the solution vessel. A little desiccator-grease is used to insure an air-tight joint.

**The Measurement.**—(For diagram of the apparatus see Fig. 5. The calcium chloride tube D is omitted in our final apparatus.) Measurements are made on 3 different solutions, the blank, the standard, and the "unknown."

*The blank* is run first. This solution may be used for an indefinite number of determinations. It is prepared according to the method for an "unknown" sample as above, except that the monazite sand is omitted. The solution bottle containing the blank is attached to the line in place of Bottle S shown in the diagram. The pump is started, Cocks 1, 3, 4 and 5 are opened wide, Cock 6 is opened wide between S and I, and then Cock 2 is opened between Cock 1 and X. The cock admitting dry air to the insulation chamber (shown in Fig. 4 only) is then opened until the inlet tube through the calcium chloride solution is allowing bubbles to pass in slowly, at the rate of about 10 per minute. Cock 3 is then gradually closed until half the inlets of the pressure regulator are admitting air. We have the regulator so adjusted that the manometer, M, which contains olive-oil, then shows a difference between the pressure in Bottle B and the atmospheric pressure of 11.5 cm. This is best for the reasons given above. Under these conditions air bubbles through the monazite solution at a rate sufficient to stir it rapidly and thoroughly. The time of discharge of the electroscope is then noted.

*The Standard.*—Cock 2 is turned so as to admit air through the side-tube and close the line to the pump. The standard solution is substituted for the blank. Cock 6 is opened between the solution and the pump and a moderate stream of air drawn through the solution for 6 minutes to rid it of radium emanation. The cocks are then adjusted exactly as they were for the blank and readings of the time of discharge taken until constant within the allowable limits for the degree of accuracy desired.

*The Unknown.*—Exactly the same procedure is followed as for the standard.

The ionization chamber is then evacuated for  $\frac{1}{2}$  hour and the pump stopped.

**Calculation of Results.**—The percentage of thorium in the "unknown" may be calculated from the equation,

$$X = A \frac{T_s(T_b - T_u)}{T_u(T_b - T_s)},$$

where  $X$  is the percentage of thorium in the unknown,  $A$  the percentage of thorium in the standard,  $T_s$  the time of discharge of the electroscope by the standard,  $T_u$  the time of discharge of the electroscope by the unknown, and  $T_b$  the time of discharge of the electroscope by the blank. The percentage of thorium in the standard is determined by gravimetric analysis.

## Results.

In the table below are given the results of a series of determinations, showing the separate results of the triplicate analyses of each lot by our emanation method, and the average result from the triplicate analyses of each lot by the gravimetric method of Carney and Campbell. The agreement of the results obtained by our emanation method with those obtained by the gravimetric method is very close.

## Suggested Further Improvement.

The transfer of the viscous solution of the fused mass in 80 % ortho-phosphoric acid from the platinum crucible to the glass "solution vessel" should be eliminated for the following reasons: (1) it is difficult to carry out successfully, even after much practice; (2) it consumes time, requiring about ½ hour; (3) probable loss of some thorium X on the surface of the platinum and practically inseparable from it even by washing a great number of times. These objectionable features can easily be avoided by the use of a platinum vessel of such size and shape as will allow the final electroscopic determination to be made with the solution in it instead of in the special glass vessel we have used. We suggest, therefore,

that if a great many analyses are to be made, a special platinum vessel be used. Fig. 8 shows the dimensions which we believe such a vessel should have, and a method of connecting the vessel to the line of apparatus.

### Comparison of Methods.

In order that a method of quantitative determination may be useful, it must give results sufficiently accurate for the purpose at hand. Our method does this. In addition to accuracy, the next most desirable feature in a method is speed. In this respect our method is far superior to any other; a complete analysis by any gravimetric method requires approximately 20 hours, whereas our method requires somewhat less than 8 hours. The technique involved is extremely simple except when the transfer from platinum crucible to glass vessel is made, and, as has been suggested above, that would probably not be done if a great many determinations were to be made.

The disadvantages inherent in the emanation method as compared with gravimetric methods are (1) the apparatus required is somewhat costly; (2) the electroscope must be attached to a support practically free from vibration; (3) the electroscopic determinations must be made in a room free from unusual radio disturbances. If a great many analyses were to be made, these disadvantages could be disregarded, since the saving in time attained by the use of this emanation method would soon more than compensate for the initial cost and for the inconvenience in installing and protecting the apparatus.

### Summary.

The main sources of error in Cartledge's emanation method of determining thorium in monazite sand apparently were adsorption of thorium X by suspended matter in final solutions, by filters, and by walls of vessels used. We have avoided these by producing a complete solution of the sand without filtration and in a single vessel. This involves (a) fusion of the sand with metaphosphoric acid and potassium hydrogen fluoride; (b) solution of the resultant mass in hot 80 % orthophosphoric acid. Other improvements made are (1) use of a highly efficient form of vessel to contain

Fig. 8.—Platinum "solution vessel" and connections ( $\frac{1}{2}$  actual dimensions).

A—Outlet tube (brass); B—Inlet tube (brass); C—Thumb-screws (3); D—Cover plate (brass); E—Brass circle; F—Cemented joint; G—Glass tube; H—Rubber washers; I—Platinum vessel; J—Jets (4).

the solution during deëmanation; use of an automatic regulator to maintain constant pressure in the ionization chamber during measurements; maintenance of optimum pressure gradient along air-current line through the measuring apparatus, thus assuring minimum error on account of pressure variations, and maximum speed of measurement; protection of the insulation of the electroscope by means of a current of dry air. Analyses by this method gave results agreeing very well with results obtained by gravimetric methods, and required much less time for each determination.

In concluding, the writer wishes to express his sincere appreciation of the valuable criticisms of Dr. Herbert N. McCoy at whose suggestion this research was taken up.

## THE HEAT OF FORMATION OF SILVER IODIDE.

BY HUGH STOTT TAYLOR AND WILLIAM THEODORE ANDERSON, JR.

Received March 29, 1921.

A discrepancy, amounting to 600 calories, exists between the determinations of the heat of formation of silver iodide as measured by Jones and Hartmann<sup>1</sup> using electrometric methods and the calorimetric determinations of Braune and Koref.<sup>2</sup> The values obtained are 14,565 and 15,100 calories respectively, so that the divergence represents a difference of some 4% which is much greater than would be anticipated from the reproducibility of either set of experimental measurements. Certain electrometric determinations by Taylor<sup>3</sup> and Perrott, involving the iodides of silver, lead and cadmium, have shown agreement with the calorimetric data of Braune and Koref and favor the adoption of the higher value for the heat of formation of silver iodide.<sup>4</sup>

<sup>1</sup> Jones and Hartmann, *THIS JOURNAL*, 37, 752 (1915).

<sup>2</sup> Braune and Koref, *Z. anorg. Chem.*, 87, 175 (1914).

<sup>3</sup> Taylor, *THIS JOURNAL*, 38, 2295 (1916); Taylor and Perrott, *ibid.*, 43, 484 (1921).

<sup>4</sup> Since the communication of the present paper an article by O. Gerth has appeared in *Z. Elektrochem.*, 27, 287 (1921), in which new electrometric measurements of the free energy and heat of formation of silver iodide have been made. By substituting a direct experimental method in place of a calculation of liquid junction potentials in the silver|silver iodide|iodine cells, Gerth has demonstrated that it is in the calculation of such liquid junction potentials that the discrepancy above mentioned has arisen. The value obtained by Gerth for the heat of formation of silver iodide is 15158 calories, in good agreement with the value of 15150 calories obtained by one of us (H. S. T.) at an earlier date. The present communication confirms the correctness of these results and of the earlier calorimetric measurements of Braune and Koref.

The calorimetric data of Braune and Koref were obtained by measurement of the heat evolution (a) when iodine reacted with silver suspended in potassium cyanide solution; (b) when silver iodide dissolved in a similar solution. The difference between the two heat effects was taken to be the heat of formation of silver iodide. A 3 *N* solution of potassium cyanide was employed in the determinations.

Objection to the calorimetric procedure may be urged, owing to the possibility that the iodine may have entered into side reactions with the potassium cyanide solution. Some such possibilities may be illustrated by means of the equations,

If such side reactions occurred, the desired heat of formation would not be obtained unless the presence of metallic silver caused the reduction of all these oxidized compounds. Only in that case would the solution obtained be identical with that resulting from the interaction of silver iodide and potassium cyanide, as in the second part of the calorimetric measurement.

The nature and extent of the various possible side reactions must manifestly depend in part on the concentration of potassium cyanide solution employed in the determination, as well as upon the relative proportions of iodine and potassium cyanide present together during the course of the experiment. With this in mind, a repetition of the calorimetric experiments of Braune and Koref has been undertaken, using, instead of the 3 *N* cyanide solution employed by them, a 1 *N* solution. The modifying effect of dilution made itself at once apparent in the lower values obtained for the heat of solution of silver iodide. This result was to be anticipated, as, in the more dilute solution, complex formation and double decomposition would occur to a less degree. The heat effects obtained from the interaction of the silver and the iodine were, however, also correspondingly lower and, as the subjoined table shows, the net thermal effect obtained for the heat of formation of silver iodide in the more dilute solution is almost exactly that previously obtained by Braune and Koref using the stronger solution of potassium cyanide. We regard this as strong proof of the correctness of the calorimetric determination of the required heat of formation.

### Experimental.

**Apparatus.**—The apparatus used has been recently described by Taylor and Perrott<sup>5</sup> and does not therefore need to be discussed here. The method employed was essentially the same. Instead of measuring the current employed in the electrical heating of the solution for calibration purposes

<sup>5</sup> Taylor and Perrott, *THIS JOURNAL*, 43, 491 (1921).

by means of a coulometer, a measurement of the time of heating was made as well as the voltage drop over a resistance functioning as a heating element. The calibration of this resistance in terms of heating element and lead wires was carefully checked. The total resistance of the heater and leads was 10.35 ohms. The resistance of the heating element alone was 10.17 ohms. The temperature rise of the calorimeter system due to the interaction of a given weight of iodine with silver suspended in the potassium cyanide solution having been observed, the rise in temperature due to the introduction of a measured amount of electrical energy was then determined. This was followed by a measurement of the temperature rise from the solution of a given weight of silver iodide and this by a second measurement of the heat rise due to electrical energy. Thereafter the experiments were conducted in the order indicated in the table. The experiments were conducted at room temperature.

**Materials.**—Finely divided silver was prepared by igniting powdered silver oxide at 400° for several hours. This latter was obtained from high grade silver nitrate by precipitation with alkali followed by a thorough washing to remove excess of alkali and salts.

Resublimed iodine of high grade was used. It was finely powdered in a mortar before use.

The silver iodide employed was obtained by precipitation from solutions of high grade silver nitrate and potassium iodide. It was washed free from soluble salts and with ammonia to remove any possible chloride. The material was dried and used in the amorphous form thus obtained.

Very high grade imported potassium cyanide was employed, 800 cc. of a 1 *N* solution being used in the experiments.

The following table gives the experimental results obtained and the calculated values for the heats of the several reactions.

Expt.	Iodine G.	Rise in temp. °C.	Volts.	Time. Sec.	Rise on heating. °C.	Heat of reaction per mol. iodide, cal.
	3.127	0.710	8.30	480	0.849	25,500
2	2.359	0.533	8.10	300	0.506	25,290
4	2.740	0.695	8.10	360	0.681	25,370
7	3.467	0.877	8.10	360	0.677	25,455
8	1.586	0.393	10.52	120	0.375	25,310
					Mean	25,385
	AgI. G.					
3	5.336	0.276	8.10	180	0.319	10,215
5	6.077	0.323	8.10	180	0.328	10,200
6	7.131	0.380	8.10	180	0.330	10,340
					Mean	10,251

The difference in value of the two mean heat effects with iodine and silver iodide gives the desired heat of reaction  $\text{Ag} + \text{I} = \text{AgI} + (25385 - 10251)$  calories; whence  $Q = 15,134$  calories. In 3 *N* potassium cyanide solution the value obtained by Braune and Koref was 15,100 calories. Since

the latter used crystallized silver iodide it is evident that the divergence between the two is within the error of the measurement.

### Summary.

A repetition of Braune and Koref's calorimetric measurement of the heat of formation of silver iodide using 1 *N* potassium cyanide instead of 3 *N* solution as solvent for silver iodide has been made. Their result, a value of 15,100 calories per mole of silver iodide, has been confirmed.

## THE CATALYTIC INFLUENCE OF FOREIGN OXIDES ON THE DECOMPOSITION OF SILVER OXIDE, MERCURIC OXIDE AND BARIUM PEROXIDE.<sup>1</sup>

BY JAMES KENDALL AND FRANCIS J. FUCHS.

Received May 13, 1921.

### Introduction.

The results obtained by previous investigators on the decomposition of substances liberating oxygen are, for the most part, very indefinite and unsatisfactory. Particular reference may be made to the extensive work done on the decomposition of *potassium chlorate* under the catalytic influence of metallic oxides.<sup>2</sup> The decomposition temperatures recorded for *simple oxides* also vary widely.

	°C.		°C.		°C.
Ag <sub>2</sub> O	250-350	BaO <sub>2</sub>	450-825	CrO <sub>3</sub>	180-320
HgO	175-660	MnO <sub>2</sub>	210-560	CuO	800-1200

The data for *mixtures of oxides* are, in general, still more divergent. It is often impossible to correlate the results of different observers, either because the relative amounts of the components are not specified at all or because mention is made in such a way as to leave it quite uncertain whether volume, weight or molecular composition units were employed.

The present investigation is an attempt to obtain systematic data on the dissociation equilibria of silver oxide, mercuric oxide and barium peroxide, as affected by the presence of other oxides. The choice of these three oxides as experimental material was made on account of their ease of preparation and their conveniently low decomposition temperatures. It was anticipated that the results would prove of interest not only with respect to the mechanism of the reactions actually studied, but

<sup>1</sup> Condensation of a thesis submitted by Francis J. Fuchs in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Faculty of Pure Science, Columbia University, May 1920.

<sup>2</sup> See Sodeau, *J. Chem. Soc.*, 81, 1067 (1902).

also in connection with the more general problems of heterogeneous catalysis<sup>3</sup> and the action of promoters.<sup>4</sup> The data for barium peroxide, finally, are of particular importance in view of the possibility of their application to the industrial revival of the Brin process.

The results of earlier work on the dissociation of the above oxides may first be summarized.

#### Previous Work.

**Silver Oxide.**—No direct determinations of oxygen dissociation pressures below 300° have been made, although many investigators<sup>5</sup> claim that decomposition begins even below 200°. G. N. Lewis<sup>6</sup> found equilibrium pressures of 20.5 atmospheres at 302°, 32 atmospheres at 325° and 207 atmospheres at 445°. Oxygen evolution proceeded very slowly at first, but the accumulation of finely divided silver in intimate admixture with the oxide accelerated its decomposition considerably. Finely divided platinum and manganese dioxide were also shown to catalyze the reaction. To explain these results, Lewis suggested that the decomposition of the oxide takes place in two stages: (1)  $\text{Ag}_2\text{O} \rightarrow 2\text{Ag} + \text{O}$ ; (2)  $2\text{O} \rightarrow \text{O}_2$ . The slowness of the latter reaction controls the velocity of the decomposition and on finely divided surfaces the adsorbed gases may be expected to react much more rapidly.

**Mercuric Oxide.**—The oxygen dissociation pressures above 500° were first established by Pélabon<sup>7</sup> and the curve has been extended below 500° by Taylor and Hulett.<sup>8</sup> These latter investigators also examined the effect of finely divided platinum and certain metallic oxides upon the reaction, and found that while the rate of oxygen evolution was considerably increased, the equilibrium pressure was not significantly changed. The temperature at which the oxygen pressure equals 1 atmosphere is approximately 490° according to Pélabon, and 500° according to Taylor and Hulett. No difference in behavior between the yellow and the red modifications of mercuric oxide was obtained.

**Barium Peroxide.**—Hildebrand,<sup>9</sup> in a careful investigation on the thermal dissociation of barium peroxide, showed that solid solutions between  $\text{BaO}$  and  $\text{BaO}_2$  are formed, the oxygen pressure of the two saturated solutions reaching 1 atmosphere at approximately 825°. Le Chatelier<sup>10</sup> obtained a lower value, 796°. The difference is probably due to the influence of traces of water upon the reaction.

Extensive work on the effect of other oxides on the decomposition of barium peroxide has recently been carried out by Hedvall.<sup>11</sup> Nearly all of the oxides tested re-

<sup>11</sup> Hedvall, *Z. anorg. Chem.*, **104**, 163 (1918); **108**, 119 (1919). These papers were not published until the present work was well under way. Some duplication of experiments consequently occurs, but in view of the different methods employed this is in a certain measure desirable, since it offers a good means of testing the reliability of the results obtained.

duced the decomposition temperature and increased the rate of oxygen evolution considerably. In some cases (for example, with cuprous oxide) high reaction velocities were found even at temperatures below 200°. With certain oxides the effect was considered to be purely catalytic, with others formation of a compound between barium oxide and the added oxide was indicated.

**General Review.**—In few of the above investigations do the results of different workers stand direct comparison, and it is obvious that the chief cause of the discrepancies is the variable physical condition of the materials used. No doubt exists that the reactivity of a solid phase is very considerably controlled by its previous history,<sup>12</sup> and it is futile to expect a strongly ignited oxide to show the same behavior as a sample freshly precipitated from aqueous solutions and dried at a low temperature.

In all of the present work, consequently, standard and reproducible methods of preparation have been adopted. The various oxides were obtained in a finely divided state by precipitation whenever possible, and dried first in a vacuum desiccator and then in a Freas oven regulated to 140°. All oxides were dried for at least two months before use. In the event of their not attaining constant weight within that period, it was necessary to remove the last traces of firmly retained moisture by ignition. This procedure was not adopted except as a last resort, since it is evident from the literature that extreme and prolonged ignition renders the oxides more or less inert. Some investigators have claimed that non-ignited samples do not give reliable results (possibly owing to adsorbed gases or traces of water), but the data here presented do not substantiate this view, as will be seen below.

### Experimental.

It must be noted at the start that the aim of the present work is to secure a preliminary survey over a comparatively wide field rather than to obtain results of the highest accuracy for a few isolated systems.<sup>13</sup> For each of the fixed oxides examined, and for each of the mixtures of these with other oxides, the decomposition temperature has been determined at a single pressure only, namely 1 atmosphere. Variations in the barometer were found not to affect the temperature beyond the limits of experimental error.

The compositions of all mixtures are expressed in molecular percentages. Mixture of the component oxides was accomplished by mechanical agi-

<sup>12</sup> See Rideal and Taylor, "Catalysis in Theory and Practice," Macmillan Co., 1919, p. 16.

<sup>13</sup> It is planned to examine certain of the more interesting systems in greater detail in a subsequent investigation.

tation.<sup>14</sup> That this was adequate to ensure intimate admixture was proved by comparing the results so obtained with those given by co-precipitated oxides in the case of the system silver oxide:mercuric oxide. The decomposition temperatures checked throughout within the limits of experimental error. That the temperatures determined are true equilibrium temperatures for an oxygen pressure of 1 atmosphere was established for each mixture by approaching the equilibrium point from both directions, *i. e.*, with rising and with falling temperature. Reproducible values, within experimental errors, were consistently obtained. In certain cases a slight difference apparently existent on first trial between the values recorded for rising and for falling temperatures was found on further examination to be due to the slowness with which equilibrium was attained. By decreasing the rate of temperature change, such differences could be proportionately diminished until they became, to all intents and purposes, negligible.

**Description of Apparatus.**—The apparatus used is shown in the accompanying diagram (Fig. 1.) The furnace was of the crucible type (Hoskins make), the interior heating chamber being cylindrical, 12.5 cm. in diameter and 12.5cm. deep. A special

Fig. 1.

heating coil and rheostat capable of maintaining a constant temperature at any point up to 500° were employed. Temperatures were indicated on a nitrogen-filled thermometer<sup>15</sup> of the Tycos type, reading to 500° and graduated for 75mm. immersion.

<sup>14</sup> The separate oxides were first ground in a mortar to break up any caked masses. Every oxide employed was thus reduced to an approximate fineness of 100 to 200 mesh before use. The two oxides were then shaken up together in a closed test-tube until the mixture was apparently uniform. This was followed by a second light grinding in a mortar, after which the mixture was again thoroughly shaken.

<sup>15</sup> The decomposition temperatures obtained were, in general, higher than was expected when the investigation was commenced. It is recognized that in many systems,

The bulb of the thermometer consequently occupied the central position in the heating chamber.<sup>16</sup> The thermometer was calibrated while in position at the usual fixed points, and the standardization checked at intervals throughout the work.

The oxides under examination were enclosed in a thin-walled bulb of Jena glass, 25 mm. in diameter, joined to a capillary stem. The mixture was introduced into this reaction bulb through a short side tube, which was then sealed off. The extension of the capillary stem was bent, as indicated in the figure, to form a manometer, a mercury-seal stopcock for evacuating and charging with oxygen being also attached as shown. Benzyl benzoate (an inert, non-hygroscopic, non-volatile liquid of low density) was employed as manometer liquid, its movement on an attached millimeter scale being observed through a lens. An asbestos screen prevented radiation of heat from the furnace to the manometer.

A comparison bulb, with a blank charge of silica and a free volume as nearly as possible equal to that of the reaction bulb, was placed directly beside it in the heating chamber. This comparison bulb was attached to a second manometer, exactly similar to the first. Both bulbs were very carefully cleaned and dried before use.

**Manipulation.**—Before a determination was begun the two charged bulbs (already in position in the furnace) were filled with pure oxygen under atmospheric pressure through the stopcocks, and the benzyl benzoate in the two manometers adjusted to the same level. The temperature of the furnace was then raised very slowly and uniformly, and the change in level of the manometers noted. So long as nothing occurred in the reaction bulb, both liquid columns moved at uniform rates owing to the expansion of the enclosed oxygen. The ratio of these rates (very nearly unity, since the free volumes of the two bulbs were made as nearly equal as possible) was carefully established. As an arbitrary standard of unit volume change, a rise of 10 mm. in the comparison-bulb manometer (corresponding to a temperature change of approximately 2°) was fixed upon. As often as this unit volume change was indicated, the two stopcocks were opened to bring the systems back to atmospheric pressure, the temperature rising very gradually all the time.

Readings were continued in this way until the reaction-bulb manometer showed an abnormal volume change, indicating that evolution of oxygen had begun. The temperature was still allowed to rise slowly for about 50°, and the "rate of decomposition" arbitrarily measured by comparing the movements of the two columns. The current was then reduced where the curves are above 300° throughout, a thermocouple would have afforded a more convenient and accurate method of temperature measurement. In view of the inadvisability of changing the method when half-way through the work, however, the original set-up was retained.

<sup>16</sup> The uniformity and constancy of temperature within the heating chamber were carefully tested. It was found that while a small temperature gradient existed at different heights, yet the temperature at different points near the center of the chamber remained constant and uniform, well within the experimental limits of accuracy, over extended periods of time. For very accurate determinations, a liquid bath would of course be preferable, but for the present work the air-bath here employed proved perfectly satisfactory.

sufficiently to cool the furnace gradually. Oxygen continued to be evolved for some time, as could be seen from the opposed volume changes in the two manometers, but as the temperature slowly fell a normal contraction was finally established in the reaction bulb. The temperature at which this first occurred was noted and compared with that at which oxygen evolution commenced. After the technique of the method had been mastered, these two temperatures in any single determination rarely varied by more than  $2^{\circ}$  to  $5^{\circ}$ . The experiment was repeated with new charges of oxides and with varying rates of heating and cooling until the equilibrium point had been satisfactorily fixed.

The results obtained for the various systems examined may now be presented. The first series, in which the decomposition of silver oxide is studied, is taken up somewhat in detail in order to make clear, certain points in the experimental procedure. The remaining systems are more briefly reported upon and subjected to a general discussion later.

#### The System $\text{Ag}_2\text{O} : \text{HgO}$ .

*Silver oxide* was prepared by addition of a saturated solution of barium hydroxide to a warm solution of recrystallized silver nitrate in distilled water free from carbon dioxide. The precipitate was washed until free from barium hydroxide and nitrate, then carefully dried. Particular precautions were taken to prevent absorption of carbon dioxide at any stage of the preparation.

*Mercuric oxide* was obtained in a similar way by precipitation from hot solutions of mercuric chloride and barium hydroxide. The red precipitate was repeatedly digested with boiling water, filtered under suction and carefully dried.

Ag <sub>2</sub> O in mixture. %.	Equilibrium Temperature ( $p_{\text{O}_2} = 1 \text{ atm.}$ ).			Relative rate of decomposition. $304^{\circ}$ .
	Rising. °C.	Falling. °C.	Mean. °C.	
100	254	254	254	1.0
90	245	245	245	2.0
50	231	230	231	7.0
10	249	250	250	10.0
0	429	432	431	....

The first column in the above table shows the molecular composition of the oxide mixtures used. The average decomposition temperatures for 1 atmosphere of oxygen, as obtained with rising and with falling temperature, follow. The mean of all results obtained is given in the fourth column. The last column indicates the catalytic influence of the added oxide (mercuric oxide) on the decomposition of the silver oxide at a fixed temperature,  $304^{\circ}$  ( $50^{\circ}$  above the decomposition temperature of pure silver oxide). These relative decomposition rates were obtained by directly comparing the excess movements in the manometer levels for reaction bulbs containing the pure oxide and the different mixtures at this temperature, correcting for the various amounts of silver oxide present in each bulb.

The results obtained for pure silver oxide were in agreement with those of G. N. Lewis.<sup>6</sup> When the oxide was first heated, oxygen evolution was extremely slow below  $300^{\circ}$ ; above this temperature it became increasingly more rapid. On subsequent heatings, decomposition was markedly

accelerated by the traces of finely divided silver already present.<sup>17</sup> The results here given all refer to fresh samples of oxide. Although it was necessary to perform the work with great care in order to obtain concordant results, the samples used were evidently more reactive than Lewis's preparations. We are perfectly confident, from the regularity of the results, that the temperatures given above are true "oxygen equilibrium temperatures" and that the volume changes indicated in the manometer cannot be ascribed to evolution or absorption of minute traces of water or carbon dioxide present in the oxide. Direct tests showed that exceedingly small additions of water or carbon dioxide to the oxide mixtures produced very large and irregular volume changes, the vaporization of 0.0001 g. of water involving a depression of approximately 150 mm. on the manometer scale. In none of the measurements recorded in this article was any such effect observed.

Pure mercuric oxide also showed a very small decomposition rate, which is independent, however, of the period of heating. The decomposition temperature obtained for  $p_{O_2} = 1$  atmosphere is much lower than that recorded by previous investigators, probably owing to the different methods of preparation employed.

The results for mixtures of the two oxides were more easily established. As will be seen from the figures in the final column, the decomposition temperature of silver oxide is lowered and the rate of oxygen evolution considerably increased in the presence of mercuric oxide. A series of measurements with "co-precipitated oxides" in the same proportions (obtained by adding barium hydroxide solution to a solution containing the requisite amounts of silver nitrate and mercuric chloride) gave substantially identical results, the actual mean temperatures obtained being 246°, 232° and 251° for the three mixtures tabulated above.

#### The System $Ag_2O : BaO_2$ .

*Barium peroxide* was prepared from recrystallized barium chloride by addition of sodium peroxide, the two solutions being mixed at 0° under constant stirring. The precipitated octohydrate was filtered, washed thoroughly and dehydrated by heating first to 100°, then (after standing in a vacuum desiccator over phosphorus pentoxide for two weeks) to 350°, the heating being very carefully conducted in order to ensure a slow rise in temperature and prevent formation of barium hydroxide.

Ag <sub>2</sub> O in mixture. %.	Equilibrium Temperature ( $p_{O_2} = 1$ atm.).			Relative rate of decomposition. 304°.
	Rising. °C.	Falling. °C.	Mean. °C.	
90	201	200	201	>4.0
50	200	198	199	>7.5
10	226	226	226	>15.0

As in the previous system, the decomposition temperature of silver oxide is lowered and the rate of decomposition markedly increased by the second oxide present. Here

<sup>17</sup> For one sample, for example, the decomposition rates at 304° for three successive heatings were 1:3:6.

the oxygen evolution from mixtures of the two oxides at the fixed temperature  $304^{\circ}$  was so rapid as to carry the manometer liquid beyond the bend of the tube. The values given above are consequently merely minima.

#### The System $\text{Ag}_2\text{O} : \text{CuO}$ .

*Copper oxide* was prepared by slow addition of 10% sodium hydroxide solution to a hot solution of carefully purified cupric sulfate. The precipitate, when completely transformed from bluish to deep black, was separated and repeatedly digested with boiling water until free from sulfate. It was then dried by heating first to  $100^{\circ}$ , then to  $280^{\circ}$ .

Ag <sub>2</sub> O in mixture. %.	Equilibrium Temperature ( $p_{\text{O}_2} = 1 \text{ atm.}$ ).			Relative rate of decomposition. $304^{\circ}$ .
	Rising. °C.	Falling. °C.	Mean. °C.	
90	249	249	249	> 3.0
50	240	241	240	> 8.0
10	249	250	250	> 50.0

In this system the temperature of decomposition of the silver oxide ( $254^{\circ}$ ) is not significantly affected; the rate of oxygen evolution, however, is enormously increased.

To test the effect of the previous history of the added oxide on the temperature and rate of the decomposition, the experiments for the equimolecular mixture were repeated with cupric oxide which had previously been ignited to a red heat several times.<sup>18</sup> The relative inactivity of such a specimen was shown by the fact that the equilibrium temperature was changed to  $252^{\circ}$ , the rate of oxygen evolution also falling off considerably.<sup>19</sup>

#### The System $\text{Ag}_2\text{O} : \text{MnO}_2$ .

*Manganese dioxide* was prepared by adding potassium chlorate in small quantities to a boiling, slightly acid solution of recrystallized manganese nitrate. The precipitate was separated off, washed repeatedly and dried first at  $100^{\circ}$  and then at  $300^{\circ}$  in an atmosphere of oxygen.

Ag <sub>2</sub> O in mixture. %.	Equilibrium Temperature ( $p_{\text{O}_2} = 1 \text{ atm.}$ ).			Relative rate of decomposition. $304^{\circ}$ .
	Rising. °C.	Falling. °C.	Mean. °C.	
90	220	220	220	> 4.0
50	229	231	230	> 4.0
10	271	272	271	10.0
0	418	420	419	...

For the 90% and 50% mixtures, the usual phenomena (lowering of decomposition temperature and increase in rate of decomposition) are again encountered. For the 10% mixture, however, although the rate of oxygen evolution at  $304^{\circ}$  is apparently greater than that of pure silver oxide, the actual equilibrium temperature is raised.

Pure manganese dioxide is found to have a definite decomposition temperature of  $419^{\circ}$ ; the rate of decomposition at that point is slow, but becomes much more rapid above  $480^{\circ}$ . Previous experimenters have obtained very discordant values for this oxide. Moissan<sup>20</sup> gives  $230^{\circ}$ ; Wright and Luff,<sup>21</sup>  $390^{\circ}$ ; Gorgen,<sup>22</sup>  $400^{\circ}$ ; Hempel,<sup>23</sup>  $470^{\circ}$

<sup>18</sup> The dissociation temperature of  $\text{CuO}$  was found by Foote and Smith, *THIS JOURNAL*, 30, 1344 (1908), to be about  $1025^{\circ}$ .

<sup>19</sup> Compare Lemoine, *Compt. rend.*, 162, 702 (1916).

<sup>20</sup> Moissan, *Ann. chim. phys.*, 21, 232 (1880).

<sup>21</sup> Wright and Luff, *Ber.*, 11, 2144 (1878).

<sup>22</sup> Gorgen, *Compt. rend.*, 110, 134 (1890).

<sup>23</sup> Hempel, *Z. Elektrochem.*, 18, 729 (1912).

to 500°; while Meyer and Rötgers<sup>24</sup> state that no dissociation is observable below 530° in air or below 565° in pure oxygen. These discrepancies are undoubtedly due to differences in the physical condition and in the completeness of the dehydration of the oxide.

#### The System $\text{Ag}_2\text{O} : \text{Fe}_2\text{O}_3$ .

*Ferric oxide* was prepared by addition of excess of ammonium hydroxide to a clear solution of recrystallized ferric chloride. The precipitate was digested with boiling water several times until free from chloride, dried by heating to 100° and finally dehydrated by ignition in a porcelain crucible.

Ag <sub>2</sub> O in mixture. %.	Equilibrium Temperature ( $p_{\text{O}_2} = 1 \text{ atm.}$ ).			Relative rate of decomposition. 304°.
	Rising. ° C.	Falling. ° C.	Mean. ° C.	
90	222	224	223	> 2.5
50	247	248	248	> 5.0
10	270	268	269	> 10.0

The results are very similar to those obtained with manganese dioxide in the preceding table.

#### The System $\text{Ag}_2\text{O} : \text{CeO}_2$ .

*Cerium dioxide* was prepared by addition of ammonium hydroxide to a solution of purified ceric nitrate. The precipitate was thoroughly washed, dried at 100°, then very slowly raised to a red heat to complete the dehydration.

Ag <sub>2</sub> O in mixture. %.	Equilibrium Temperature ( $p_{\text{O}_2} = 1 \text{ atm.}$ ).			Relative rate of decomposition. 304°.
	Rising. ° C.	Falling. ° C.	Mean. ° C.	
90	248	250	249	1.0
50	269	273	271	1.5
10	280	280	280	4.5

In this series the catalytic influence of the added oxide upon the decomposition of the silver oxide is still less pronounced than in the cases of manganese dioxide and ferric oxide. The 90% mixture gives a decomposition temperature only slightly below that of pure silver oxide, while the decomposition temperatures for the remaining mixtures are considerably higher. The rate of oxygen evolution for the various mixtures at 304° is less than in any of the previous series.

#### The System $\text{Ag}_2\text{O} : \text{SiO}_2$ .

*Silicon dioxide* was obtained by addition of hydrochloric acid to a solution of sodium silicate. The gelatinous precipitate was washed, ignited to a powder, washed repeatedly till free from salts, dried and re-ignited.

Ag <sub>2</sub> O in mixture. %.	Equilibrium Temperature ( $p_{\text{O}_2} = 1 \text{ atm.}$ ).			Relative rate of decomposition. 304°.
	Rising. ° C.	Falling. ° C.	Mean. ° C.	
90	250	251	250	1.5
50	261	263	262	2.0
10	285	284	284	5.0

The results are substantially identical with those given by cerium dioxide mixtures.

#### The System $\text{Ag}_2\text{O} : \text{CrO}_3$ .

*Chromic anhydride* was prepared by careful addition of conc. sulfuric acid to a well-stirred solution of recrystallized sodium dichromate. The precipitated chromium trioxide was separated by filtering through glass wool, washed with conc. nitric acid

<sup>24</sup> Meyer and Rötgers, *Z. anorg. Chem.*, 57, 104 (1908). See however, Askenasy and Klonowski, *Z. Elektrochem.*, 16, 107 (1910).

until free from sulfate, dried as completely as possible on a porous tile and finally heated to constant weight at 120°.

The decomposition temperatures for pure chromium trioxide given in the literature vary widely. Arctowski,<sup>25</sup> for example, claims that rapid decomposition occurs just above the melting point (180–190°), while Honda<sup>26</sup> has more recently reported a *minimum* temperature of 320°, the resultant lower oxide having the composition Cr<sub>6</sub>O<sub>15</sub>. The present experiments indicated melting of the oxide at 180° and an equilibrium temperature for  $p_{O_2} = 1$  atmosphere at 190°. Owing to the volume change involved in the change of state the manometer readings were difficult to interpret unless the temperature was varied extremely slowly. The above values are to be regarded as only approximate.

With mixtures of chromium trioxide and silver oxide containing 90% and 50% silver oxide no concordant results could be obtained. After the melting of the chromium trioxide around 180° rapid oxygen evolution was noted at about 200° with rising temperature, but with falling temperature decomposition ceased at much higher points, 225° and 245° respectively. The mixture containing 10% of silver oxide, however, gave a definite equilibrium temperature of 161°, *i. e.*, below the melting-point of chromium trioxide.

#### Mercuric Oxide Systems.

Added oxide.	HgO in mixture, %.	Equilibrium Temperature ( $p_{O_2} = 1$ atm.).			Relative rate of decomposition. 471°.
		Rising. ° C.	Falling. ° C.	Mean. ° C.	
	100	429	432	431	1.0
CuO	90	398	400	399	> 1.0
	50	380	382	381	> 2.0
	10	419	419	419	> 10.0
BaO <sub>2</sub>	90	279	281	280	> 1.0
	50	278	276	277	> 1.5
	10	282	284	283	> 7.0

	50	410	411	410	> 5.0
	10	425	423	424	> 20.0
CeO <sub>2</sub>	90	414	414	414	> 2.0
	50	430	431	431	> 2.0
	10	439	439	439	> 5.0

As in the case of silver oxide systems, copper oxide and barium peroxide both lower the decomposition temperature and increase the rate of oxygen evolution.<sup>27</sup> Copper oxide, as before, has the greater effect upon the rate of the reaction, barium peroxide the greater effect on the equilibrium temperature.

Ferric oxide and cerium dioxide again exhibit much less pronounced influence, the decomposition temperature being only slightly changed. Manganese dioxide here induces a far greater temperature decrease. The results for the 10% mixture, however, are rather uncertain.

<sup>25</sup> Arctowski, *Z. anorg. chem.*, 9, 29 (1895).

<sup>26</sup> Honda, *Science Repts. Tohoku Imp. Univ.*, 4, 897 (1915).

<sup>27</sup> A reference temperature of 471° (40° above the decomposition point of pure HgO) has been chosen for comparing rates of reaction in the above table.

Attempts were also made to examine the effect of chromic anhydride and silicon dioxide on the decomposition of mercuric oxide. With chromic anhydride, phenomena similar to those described in the silver oxide series were observed. The 90% and 50% mixtures showed rapid evolution with rising temperature immediately after fusion of the chromium trioxide, *i. e.*, below 200°. With falling temperature, decomposition ceased at much higher temperatures. The 10% mixture gave a definite equilibrium temperature of 171°.

With silicon dioxide no satisfactory results could be obtained. The 90% mixture evolves oxygen at a temperature slightly below the normal, while with the remaining mixtures, the decomposition temperature is considerably raised. No consistency could be attained, however, between results with rising and with falling temperatures.

#### Barium Peroxide Systems.

	50	345	344	345
	10	357(?)	360(?)	358(?)

The equilibrium temperature for pure barium peroxide (approx. 825°) being far beyond the limits of the present work, no column of relative rates of decomposition can be included in the above table. For all of the mixtures listed, however, the rate of oxygen evolution even below 400° was already quite rapid, so that the catalytic effect of the added oxides upon the reaction is in all cases very considerable.

The presence of copper oxide, manganese dioxide or ferric oxide lowers the decomposition temperature of barium peroxide by nearly 500°. With the 10% mixtures of the last two oxides, the results obtained were not altogether satisfactory, the figures given above being the mean of several rather divergent determinations.

With cerium dioxide mixtures, no indications of oxygen evolution were given at 520°, the limit of temperature measurement.

In the presence of silicon dioxide, decomposition of the barium peroxide was found to begin at much lower temperatures. With rising temperature, values of 247°, 295° and 309° were obtained for mixtures containing 90%, 50% and 10% of barium dioxide respectively. With falling temperature, however, these figures could not be duplicated.

#### Discussion of Results.

**Silver Oxide Systems.**—From the tables given above, it is evident that the decomposition temperature of silver oxide for  $p_{O_2}$  = 1 atmosphere is very markedly affected by the presence of other oxides. In all cases the first addition of a foreign oxide lowers the decomposition temperature. With larger amounts a minimum value is reached, while an excess of added oxide may actually raise the decomposition temperature above the normal. Invariably, however, the rate of oxygen evolution is increased.

If we are to retain the view that a catalyst, however much it may hasten

the attainment of equilibrium, cannot alter the equilibrium point of a reaction, then it is certain that the influence of the foreign oxides throughout this series is not purely catalytic, since the equilibrium point is undoubtedly changed. The increase in the rate of oxygen evolution may it is true, be ascribed entirely to adsorption effects, as indicated by Lewis,<sup>6</sup> but the wide variations in the decomposition temperature cannot be satisfactorily explained on the basis of adsorption alone. All of the results, indeed, point to the conclusion that the added oxide enters directly into the reaction.

The simplest and most plausible assumption that can be made is the formation of transient intermediate compounds between the two oxides.<sup>28</sup> Such compounds could be regarded as *salts* produced by the combination of a basic and an acidic component, and the relative instability of the salt would determine the change in the decomposition temperature. Silver oxide being characteristically basic, we might expect other basic oxides to give very unstable complexes with it. In point of fact, the decomposition temperature is lowered most considerably by barium dioxide and mercuric oxide. The complexes of silver oxide and more acidic oxides, on the other hand, might be predicted to be more stable. In line with this, we find excess of ferric, manganese, ceric and silicic oxides raising the decomposition temperature.

In the system  $\text{Ag}_2\text{O}:\text{CrO}_3$ , the formation of a salt ( $\text{Ag}_2\text{CrO}_4$ ) between the two components may be definitely established. The salt is produced in the reaction bulb just above the melting point of chromium trioxide with considerable evolution of heat and partial decomposition. With falling temperature, oxygen evolution ceases at much higher temperatures, indicating that the complex is more stable than chromium trioxide. It is still, however, slightly less stable than silver oxide.

**Mercuric Oxide Systems.**—The results for this series are substantially similar to those given by the corresponding silver oxide systems, and the same explanation may be adduced. Barium dioxide lowers the decomposition temperature very considerably, cupric oxide has less effect, ferric and ceric oxides have very little influence upon the equilibrium point. The results for chromium trioxide mixtures point to the formation of a relatively stable compound, mercuric chromate,  $\text{HgCrO}_4$ . In the same way the discordant results for silicon dioxide mixtures with rising and falling temperatures may be explained by the production of mercury metasilicate,  $\text{HgSiO}_3$ .

It is important to note that the results here obtained are in direct opposition to those of G. B. Taylor and Hulett.<sup>8</sup> The only explanation that

<sup>28</sup> Compare Lewis, "A System of Physical Chemistry," Longmans, Green and Co., 1918, vol. 1, p. 456. The formation of solid solutions might affect the results in isolated systems, but could scarcely be adduced as a general phenomenon.

can be suggested at present is that the oxides employed by these investigators were rendered inactive by previous prolonged ignition.

**Barium Peroxide Systems.**—The three oxides listed (cupric oxide, manganese dioxide and ferric oxide) all lower the decomposition temperature nearly  $500^{\circ}$ . If, as appears probable from the results of Hedvall and Zweigbergk,<sup>29</sup> barium dioxide evolves oxygen simultaneously with silver oxide and mercuric oxide in its mixtures with these two oxides, then in their presence its decomposition temperature is still further decreased. Cerium dioxide is much less active. The results for silicon dioxide mixtures are, as before, best explained by the formation of a stable silicate.

Hedvall and Zweigbergk have already obtained evidence in favor of the assumption that, in the majority of systems containing barium dioxide and a foreign oxide, salt formation is the predominant factor in controlling the decomposition. The present results are in general agreement with their data. Quantitative agreement is hardly to be expected in view of the different methods of treatment of the oxides employed. There is, besides, no evidence that the values given by Hedvall and Zweigbergk (as obtained by the determination of breaks in the heating curve) represent true equilibria. In all probability the decomposition temperatures recorded are, in general, too high.

**General Review.**—A mixture of two substances, each of which evolves oxygen when heated alone, almost always decomposes much more readily than either of its separate components. In certain cases each substance simultaneously promotes the decomposition of the other. Silver oxide and hydrogen dioxide, for example, mutually decompose one another at ordinary temperatures.<sup>30</sup> In other instances only one of the components loses oxygen. Thus the decomposition temperature of potassium chlorate is very considerably lowered by the presence of foreign oxides, the case of manganese dioxide being the most familiar. The mechanism of this reaction has been the subject of much speculation. From the work of Sodeau<sup>31</sup> it has been definitely established that the manganese dioxide must enter directly into the decomposition cycle, since a crystalline sample is transformed into a finely-divided powder in the course of the reaction.

Much of the work on the catalytic effect of foreign oxides on the de-

<sup>29</sup> Hedvall and Zweigbergk, *Z. anorg. Chem.*, **108**, 119 (1919). A convenient summary of the results obtained by these workers may be found in *Ann. Repts. Chem. Soc.*, **17**, 40 (1920).

<sup>30</sup> Various theories have been advanced to explain this reaction, Liveing's hypothesis of local energy transfer being particularly interesting. (See Rideal and Taylor, "Catalysis in Theory and Practice," Macmillan Co., 1919, p. 42. The action of other oxides on  $H_2O_2$  has recently been investigated by Loemine (*Compt. rend.*, **162**, 702 (1916)).

<sup>31</sup> Sodeau, *J. Chem. Soc.* **77**, 137, 717 (1900); **79**, 247, 939 (1901); **81**, 1066 (1902).

composition of potassium chlorate is open to question (contradiction between the results of different investigators being frequent) yet a survey of the more reliable data shows that those oxides which have been found to be most active in the present work are also most active in promoting the decomposition of potassium chlorate and hydrogen dioxide. Our knowledge of the whole subject of heterogeneous catalysis is still so elementary that it is dangerous to attempt to draw any final conclusions as to the part which the added oxides play in these processes. For the several series of systems here studied, however, the hypothesis of the formation of intermediate complexes would appear to provide a logical explanation of the experimental facts. In any quantitative study of the rate of decomposition in any particular mixture, of course, adsorption effects would also need to be taken into consideration.

In a subsequent article the practical application of the results obtained for barium dioxide systems to the Brin oxygen process will be discussed, and the effect of the simultaneous addition of more than one foreign oxide upon the temperature and rate of the decomposition investigated. In certain other reactions (*e. g.*, the oxidation of carbon monoxide to the dioxide in the purification of hydrogen<sup>32</sup>) it has been discovered that an enormous increase in the catalytic activity of a single oxide may be induced by the presence of a very small amount of a second oxide which alone may be relatively inert. In the removal of carbon monoxide as a toxic gas from air, similarly, it has been found<sup>33</sup> that mixtures of oxides (*e. g.*,  $\text{MnO}_2$ ,  $\text{CuO}$ ,  $\text{Co}_2\text{O}_3$ ,  $\text{Ag}_2\text{O}$ ) are much more efficient than any single component. If this "promoter action" is similarly pronounced in the decompositions here studied (and preliminary experiments indicate that this is the case) then the fascinating possibility arises of resurrecting the Brin process industrially by carrying out the whole cycle of operations at ordinary temperatures. Whether this is feasible in practice remains, of course, to be tested.

### Summary.

The effect of foreign oxides upon the temperature and rate of decomposition of silver oxide, mercuric oxide and barium peroxide under an oxygen pressure of one atmosphere has been experimentally investigated.

In almost all of the systems examined, the added oxide induces a considerable change in the decomposition temperature. Most commonly there is a marked lowering in this point, thus (to cite an extreme case) an equimolecular mixture of barium dioxide and cupric oxide has an oxygen equilibrium pressure of 1 atmosphere at  $322^\circ$ , approximately  $500^\circ$  below the decomposition temperature of pure barium dioxide. In a few systems a

<sup>32</sup> Rideal and Taylor, *op. cit.*, p. 29 *et seq.*

<sup>33</sup> Lamb, Bray and Frazer, *J. Ind. Eng. Chem.*, 12, 213 (1920).

comparatively small rise in the decomposition temperature is indicated. In all instances, however, the rate of oxygen evolution is significantly increased.

It must be emphasized that the decomposition temperatures recorded refer to true equilibrium conditions, concordant values being obtained with rising and with falling temperature. Disagreement with the results of previous investigators is, in certain systems, very evident. Much of the earlier work in this field is, however, not directly comparable, owing (in large measure) to differences in the physical condition of the materials employed. As far as possible, standard and reproducible methods of preparation have here been adopted.

The results obtained have been tentatively ascribed to the formation of unstable intermediate compounds between the two oxides present. The increased rates of decomposition may be referred to adsorption effects, but the large temperature changes point strongly to the actual participation of the added oxides in the reaction. Direct evidence was given in certain mixtures of the production of relatively stable complexes.

A later article will continue the study of systems of the types here examined, with particular reference to the Brin oxygen process and the important question of "promoters."

## THE PREPARATION AND STUDY OF THE RARER ALKALI BROMATES. RUBIDIUM BROMATE.

BY HAROLD D. BUELL AND C. R. McCROSKY.

Received June 8, 1921.

Some time ago the preparation and some of the properties of cesium bromate were discussed in *THIS JOURNAL*.<sup>1</sup> In the present paper the work has been extended to the rubidium bromate, which like the cesium salt, has had no mention in chemical literature. Some further data on cesium bromate have been added in this paper.

### Preparation of Rubidium Bromate.

A sample of rubidium chloride, of doubtful purity, was converted into the alum<sup>2</sup> and this was recrystallized several times. The solution of the pure alum was digested with an excess of barium carbonate on the hot plate for several hours, and after filtering, treated with barium hydroxide and then with carbon dioxide. After again filtering, the solution gave no tests for traces of aluminum, barium, potassium, cesium or sulfate.

<sup>1</sup> McCrosky and Buell, *THIS JOURNAL*, 42, 1786 (1920).

<sup>2</sup> Browning, "Introduction to the Rarer Elements," John Wiley and Sons Co., 1919, p. 15.

It was now treated with an excess of pure bromic acid and allowed to crystallize. The product was recrystallized three times for analysis.

### Analysis of the Substance.

The finely powdered salt was dried at 115° until it became constant in weight. The results recorded in the following tables are those obtained from analyses carried out in the same manner as those made in the examination of cesium bromate.<sup>1</sup>

<sup>3</sup> Buchanan, *J. Ind. Eng. Chem.*, 12, 448 (1920).

### Melting Points.

The melting points of cesium and rubidium bromates were determined by the use of a platinum-platinum-rhodium thermocouple, inserted in a bath of fused anhydrous zinc chloride.<sup>4</sup> The salts were placed in capillaries in the bath near the couple. The thermocouple was calibrated by comparing with the accepted melting points of pure potassium dichromate (396°), silver bromide (427°) and thallous chloride (429°). The melting point of cesium bromate was found to be approximately 420°, and that of rubidium bromate 430°. Potassium bromate, even after careful purification, was found to melt at 405°, well below the accepted value of 434°. The same value was obtained when the latter salt was sealed in the capillary. The values, above, are the averages, in each case, of 8 or 10 readings, all of which checked closely.

### Crystalline Structure.

The authors are indebted to Dr. Charles H. Richardson, head of the Department of Mineralogy of Syracuse University for the following data on the crystalline structure of the two bromates.

The crystals from the water solution of both bromates were small and cube-like, but the polarizing microscope showed that they were not isometric (or isotropic) but anisotropic. Both bromates gave perfect uni-axial interference figures, showing definitely that they crystallize in either the tetragonal or the hexagonal system. Under the microscope the hexagonal system may yield crystals, cube-like in aspect, but this is not true in the tetragonal system. In a few instances the outlines of the crystals showed, with reasonable certainty, that they belonged to the hexagonal system. Unsuccessful attempts were made to secure crystals large enough to measure the interfacial angles on a reflecting goniometer. From the work done, however, it would seem that both the cesium and rubidium bromates belong to the hexagonal system. Examination showed that they were optically positive.

For determining the index of refraction of the two bromates a definite series of immersion fluids, commonly used as standards, was used. When compared with methylene iodide, with an index of refraction of 1.74; carbon disulfide, 1.768; sulfur dissolved in methylene iodide, 1.83; molten sulfur, 1.93;  $\alpha$ -sulfur, 1.95; and  $\beta$ -sulfur, 2.038; it was found that the bromates had a still higher index of refraction. The index of refraction of yellow phosphorus (2.144) was a little below, while the value for mercuric iodide crystals from an aniline-quinoline solution (2.22) was a little above that of the bromates. It appears therefore, that the index of refraction of the bromates falls between 2.144 and 2.22. Further work is necessary for the absolute determination of these indices.

### Summary.

Rubidium bromate is prepared by a method similar to the one used in the preparation of cesium bromate.

<sup>4</sup> THIS JOURNAL, 40, 1662 (1918).

Some comparative solubilities of cesium and rubidium bromates are given.

The approximate melting points and data on the crystalline structure of the bromates are included in this work.

**MANGANESE IN THE CATALYTIC OXIDATION OF AMMONIA.**

BY CHARLES SNOWDEN PIGGOT.

Received June 9, 1921.

The purpose of the investigation<sup>1</sup> was to study the use of manganese as a constituent of catalysts for the oxidation of ammonia. Inasmuch as a considerable amount of work had been done on the use of manganese dioxide mixed with other metallic oxides as a catalyst for the oxidation of carbon monoxide,<sup>2</sup> it was decided to investigate these and similar mixtures for the catalytic oxidation of ammonia.

However, it was anticipated that these finely divided active catalysts would, like finely divided platinum, prove to be too active for this purpose and consequently show a low efficiency. It was thought that this could be overcome if these materials were combined as alloys and superficially oxidized.

The investigation is, therefore, divided into two parts: first, the study of the oxide catalysts; and second, the study of manganese alloys.

### Oxide Catalysts.

**Manganese Dioxide.**—Ordinary manganese dioxide was found to have little catalytic effect on the oxidation of ammonia, but when in a state of fine sub-division it acted as a catalyst for this reaction.

It was prepared by adding powdered potassium permanganate to cold conc. sulfuric acid and allowing the permanganic acid thus formed to decompose spontaneously into manganese dioxide and oxygen.<sup>3</sup> It was then washed by decantation until free from sulfates, filtered and partially dried on a water-bath. When the water content had been reduced to about 50% it was subjected to a pressure of 2818 kg. per sq. cm. for 24 hours. The resulting cake was broken up and completely dried in a stream of oxygen at 130–140°. When tested<sup>4</sup> on ammonia this material showed considerable catalytic effect, as is shown in Table I following.

<sup>1</sup> This investigation was carried on throughout part of 1919 and 1920.

<sup>2</sup> Lamb, Bray and Frazer, *J. Ind. Eng. Chem.*, 12, 213–21 (1920); Rogers, Piggot, Bahlke and Jennings, *THIS JOURNAL*, 43, 1973 (1921).

<sup>3</sup> Fremy, *Compt. rend.*, 82, 1231 (1876).

<sup>4</sup> The difficulties associated with the quantitative estimation of oxidized nitrogen as described later in this article applied equally here.

TABLE I.—MANGANESE DIOXIDE.

Temp. of catalyst = 800°. NH<sub>3</sub>, 300 cc./min.

Time of contact = 0.05 sec. Air, 3200 cc./min.

Time of run 50 minutes. 1.0 cm. layer.

38.63	30.64	79.31	pressed
38.85	29.46	75.84	pressed

Though functioning catalytically the oxide undergoes some change during the reaction. The color changes from black to a light yellowish-brown, the material having changed apparently from the dioxide to a lower oxide of manganese.

**Mixture of Oxides.**—Precipitated manganese dioxide when mixed with various proportions of silver oxide or copper oxide or with both of these oxides produces a catalyst which is quite active in the oxidation of ammonia.

The manganese dioxide used for these mixtures was prepared by treating a concentrated solution of potassium permanganate at 80° with methyl alcohol, filtering on a Büchner funnel, washing and drying to about 50% water content, this latter being determined by analysis. A weighed quantity of this paste was made into a fine suspension in water and the proper amount of silver added in the form of silver nitrate solution. Silver oxide was then precipitated on the manganese dioxide by means of a slight excess of strong sodium hydroxide solution. The two oxides quickly settle out as a single precipitate. When silver and copper were used together they were added in the form of their nitrate solutions as above. When copper alone was added it was usually added as the sulfate and precipitated by sodium carbonate. In any case the precipitates were washed by decantation until free from alkali or sulfates, filtered with suction and dried in a current of oxygen at 130–140°. The dry cake was broken up, screened to convenient size and used for testing.

Catalysts so made have proved to have considerable activity, are very porous, thus offering a very large surface, and are quite resistant to the high temperatures of the reaction, *i. e.*, they show no tendency to sinter together even when the temperature is raised to 1000° or more. The activity can be more or less closely controlled by the method of preparing the catalytic mixture; mixtures containing the constituents in a very fine state of subdivision and in intimate contact being much more active than those in which the reverse is true.

The disadvantages of such catalysts are softness, tendency to crumble and produce fines which clog the gas passages, their tendency to take

up moisture due to their extreme porosity, the fact that in contact with a liquid they disintegrate, and that liquid nitric acid will dissolve out the silver or copper oxides. Tables II, III and IV show the results of the tests on these oxide mixtures.

Manganese dioxide when prepared by the Fremy method and mixed with silver oxide, copper oxide, or mixtures of both, produces materials which are such vigorous oxidizing catalysts that the ammonia is largely converted into nitrogen and water, with a consequent low efficiency for nitric acid.

TABLE II.—MIXTURES OF OXIDES.

Composition:  $\text{MnO}_2$  (Fremy), 71.43%;  $\text{CuO}$ , 21.43%;  $\text{Ag}_2\text{O}$ , 7.14%; dried at  $135^\circ$ . Time of contact, 0.11 sec.  $\text{NH}_3$ , 300 cc./min. Air, 3200 cc./min. Temp. of cat.,  $800^\circ$ . Time of run, 50 min. 1.8 cm. layer.

In.	$\text{HNO}_3$ g. Out.	Efficiency %
38.63	18.85	48.77
38.77	21.10	54.41

Manganese dioxide prepared by treating hot ( $100^\circ$  approx.) potassium permanganate solution with methyl alcohol is relatively coarse in structure and consequently not so active. This type was used in preparing mixtures of which the following is a fair example. Though not so active an oxidizing catalyst it gave greater efficiencies based on the nitric acid yield.

TABLE III.—MIXTURES OF OXIDES CONTAINING COARSER MANGANESE DIOXIDE.

Composition:  $\text{MnO}_2$ , 60%;  $\text{CuO}$ , 40%; dried at  $140^\circ$ . 4 cm. layer. Time of contact, 0.2 sec.  $\text{NH}_3$ , 300 cc./min. Air, 3500 cc./min. Temp. of cat.,  $800^\circ$ . Copper precipitated as carbonate.

In.	$\text{HNO}_3$ g. Out.	Eff. %
38.10	33.80	88.96
38.60	37.74	97.71
38.62	33.79	87.50
38.62	38.29	96.57
38.23	36.69	95.98

Manganese dioxide was prepared as for the  $\text{MnO}_2$ - $\text{CuO}$  mixture described above and mixed with silver oxide, the latter being precipitated on the former from the nitrate solution by sodium hydroxide. The efficiency, not high at first, rapidly decreased. The time of exposure of each charge was 6 hours.

## II. Manganese Alloys.

The variable valence of manganese together with its other chemical properties, recommended it as a good catalytic agent if brought into intimate contact with suitable promoters. It was thought that this intimate contact might well be obtained in an alloy. The advantages of an easily workable metallic catalyst are many; as for instance the possibility of making connections and reaction chambers of it and the weaving of gauzes for the actual contact material.

S. F. Zhemchuzhnii and V. K. Petrashevich<sup>5</sup> state that they have been able to cold draw a manganese alloy of the composition 1.1% Fe, 3.53%-Cu, 0.50% Al, 0.12% Si and 94.75% Mn, to a wire 1 to 1.5mm. diameter without annealing between passes. None of the alloys used in this investigation, though more or less ductile, exhibited such ductility as indicated by the above.

Some 6 months of the investigation were devoted to the problem of obtaining a manganese alloy relatively free from impurities (Fe, C, Si). This proved very difficult, and has not been entirely solved up to the present time.

Crucibles of carbon, silicon, or porcelain were of course out of the question, and the usual magnesite crucibles proved to be too porous and frail for melting satisfactorily 200- to 400-g. charges of material.

Alundum crucibles tended to adsorb large quantities of the molten manganese, forming a slag coating which was extremely hard. This difficulty was only partially overcome by lining the crucibles with magnesium oxychloride. The most satisfactory crucibles so far tried were made from a magnesite-iron oxide mixture of about the same composition as that used in making the ordinary magnesite brick for iron smelting purposes.

When using a molybdenum-wound "hydrogen" furnace, the hydrogen formed many "blow holes" in the ingots, the small magnesite crucibles being too frail to permit pouring.

With an electric-resistance vacuum furnace the volatilization of the manganese

<sup>5</sup> Zhemchuzhnii and Petrashevich, *Bull. acad. sci.*, 1917, 863-76.

was excessive even when the furnace was filled with hydrogen under slightly reduced pressure.

The best results have been obtained by using the magnesium oxide—iron oxide crucible as stated above, and a Seger gas furnace. The melt was covered with fused sodium borate as a flux, and the charge was protected as much as possible from contact with the furnace gases by enclosing the crucible in a fire-clay muffle. The best obtainable thermit-process manganese, and electrolytic copper and silver were used. A comparatively large charge was melted and the best of the metal poured into a steel mould coated with graphite, giving a rod 12 mm. in diameter by 15cm. long, which required about half the metal of the melt. This rod was then turned on a lathe and the turnings after oxidizing were used as catalysts.

Considerable time was devoted to various methods of oxidizing metallic surfaces so as to give a firm and adherent coating as well as one of maximum activity. Various gauzes, especially those containing manganese were investigated with this end in view, the final result being the method of electrolytic oxidation described below.

The preliminary oxidation of the catalysts was done electrolytically, the turnings being placed in a porous cup and made the anode by thrusting a platinum wire into the mass. The electrolyte used was 0.1 *N* sodium hydroxide solution. A current of 0.5 to 1.0 ampere was passed for from 3 to 4 hours, the potential across the electrodes being 10.0 to 15.0 volts.

This treatment caused the material to be thoroughly oxidized superficially, with a very adherent dark brown coating. After being washed and dried it was ready for testing.

It was found in the course of the investigation that it was not essential to oxidize the alloys before using, for like the platinum gauzes they could be "activated" by exposure at 600–700° to the ammonia-air mixture, for several hours. However, the electrolytic method was more rapid and satisfactory, and was the usual method employed.

#### Analytical Difficulties.

A very troublesome problem was the devising of a suitable testing and analytical method, and the building of a satisfactory apparatus to put the same into operation. The chief difficulty was to prevent as much as possible the decomposition of the nitric oxide once formed and to bring about its *complete* oxidation to nitrogen dioxide or the higher oxides and to insure their absorption. This was accomplished by using oxidation towers of large volume, water vapor in the form of saturated steam, and vigorous agitation by means of high-speed stirring.

Nitrogen oxides are very difficult to absorb, as is also ammonium nitrate, the latter especially so when in the condition of a colloidal "smoke." Efforts were first directed toward absorbing the oxides of nitrogen in towers of various types. Soda-lime, sodium hydroxide, water, hydrogen peroxide, potassium permanganate solution, conc. sulfuric acid, etc., were tried separately and in conjunction.

The efficiency was to be calculated on the basis of the oxygen used up. This involved accurate measurement of flows of affluent and effluent gases and absolute oxidation and absorption of the nitrogen oxides. All such methods proved unavailing. Various types of flow-meters were made and tried but none could be devised which

would measure accurately the varying concentrations of the various oxides of nitrogen which passed through it, without being affected thereby.

Conc. sulfuric acid may absorb oxides of nitrogen quantitatively, as stated by Nernst, in small quantities and on long exposure; but it was found entirely inadequate under the conditions of this investigation.

### Apparatus.

The apparatus used in the investigation is shown diagrammatically in the accompanying drawing. *A, A* are two 10-liter aspirating bottles which serve to give volume, and allow time for the oxidation of nitric oxide to nitrogen dioxide or the higher oxides. A jet of low-pressure steam is passed in at *S* which furnishes water for the formation of nitric acid which is drawn off at *N*. *B* is a Hoskins electric furnace and *C* the catalyst, supported on a Witt plate, the whole being surrounded by an auxiliary heating unit which serves to start the reaction and to maintain it at the proper temperature. The clay combustion tube which contains the catalyst passes through

the two heating units and is provided in one side with a porcelain tube through which the mixed gases enter. It is connected below with a water-cooled condenser *D* which serves to cool the products of the reaction quickly. The catalyst bed is provided with a small quartz bulb in which is a thermocouple whose wires lead to a Leeds and Northrup compensating potentiometer. *E* is a coil condenser, which serves as a preheater of the mixed gases, through the jacket of which steam is passed at from 140 to 210 g. per sq. cm. pressure. *P* is a mixing chamber for the ammonia and air, while  $F_{NH_3}$ ,  $F_{Air}$  are flow-meters for the measurement of these gases respectively. *G* is the absorption apparatus consisting of two battery jars with cold water circulating in the annular space between. The inner jar contains sodium hydroxide solution which is kept stirred by the stirring mechanism *H* which revolves at a speed of 10,000–20,000 r. p. m., the stirring head *K* being heavily gold plated. This stirring head is so con-

structed that the entering gases and vapors are sucked up at the center and thrown out through the radial holes, which at the speed of operation brings about an emulsoid condition which insures a very thorough mixing and accomplishes complete absorption of the vapors of nitric acid and the oxides of nitrogen. Baffle plates are provided to prevent a circular motion of the liquid and to prevent the latter from being thrown out of the container. It was found necessary to cool the solution, as otherwise the heat produced by the rapid stirring during a run was sufficient to bring the solution almost to its boiling temperature. The water (usually slightly acid) produced by the oxidation of the ammonia is collected and drawn off at *M*. If desired, an auxiliary stream of air could be passed in at *O*, but this was seldom used.

The flow-meters were carefully calibrated at average room temperature, 25°, and were used only on the gas with which they had been previously calibrated.

### Methods of Testing.

In making a run the following procedure was usually adopted. 1000 cc. of *N* sodium hydroxide solution was placed in the adsorption apparatus *G*; and the catalyst, placed at *C*, heated externally to about 600°. The furnace *B* was heated to its maximum temperature (950–1000°) and steam passed in at *S* and through *E*. Ammonia from a steel cylinder, and air, measured by their respective flow-meters, were passed into the mixing chamber *P*. The quantity of air mixed with the ammonia at this point was usually only sufficient to furnish a volume of oxygen equal to that of the ammonia; the remaining air for the completion of the reaction being passed through the other air flow-meter and down through the hot furnace *B*, meeting the ammonia-air mixture just before contact with the catalyst. This air was heated by the furnace *B* to about 300° to 400°, while the mixture passing through the preheater *E* was heated not above 90–100°, thus ensuring no decomposition of the ammonia. The liquids which collect at *M* and *N* were drawn off from time to time and added to the sodium hydroxide solution at the end of the run. At first runs of 100 minutes were made, but later 50-minute runs were used and this time was maintained throughout the remainder of the investigation.

The gases issuing from the second reaction chamber were by-passed and allowed to escape for some time until the run became stabilized and everything was working properly before a test was begun.

The ammonia entering the apparatus was calculated as g. of nitric acid,  $\text{HNO}_3$ , due correction being made for temperature at the flow-meter. At the end of the run the solution in *G* was measured and its normality determined by titrating a 10.00cc. sample with *N* hydrochloric acid using phenolphthalein as indicator. From this the g. of nitric acid produced was obtained and the percentage efficiency calculated.

To the 10.00cc. sample of solution from *G*, taken above, when just neutralized, was added an additional 10.00 cc. of *N* sodium hydroxide solution, any ammonia thus liberated was boiled off and the solution back titrated with *N* hydrochloric acid. In this way the quantity of ammonia

which passed the catalyst unoxidized was determined and could be corrected for. This procedure however was not always necessary as even a slight trace of ammonia passing the catalyst would fill the reaction chambers with a dense white cloud of ammonium nitrate and thus indicate its presence.

A number of preliminary test runs were made to determine the effect of glass, quartz, porcelain, and other materials on the decomposition of ammonia and the oxides of nitrogen when formed. All those materials were found to favor the decomposition to a greater or less extent, quartz being the most active catalyst for this decomposition.

A clay combustion tube was found to give the least decomposition. Condensed results of this investigation are shown briefly in the following tabulation. The same catalyst was used throughout.

Rate of NH <sub>3</sub> , 80 cc./min.		Eff. %
Temp. of cat. C.	Material.	
900	Quartz	33.40
830		34.10
800		40.48
650		39.91
630	Pyrex	35.50
700		44.10
800		59.10
845	Clay	70.70
850		75.60
900		73.60

After the clay tube was adopted an idea of the effect of heat and time of heating, on the decomposition of ammonia, was obtained by locating the catalyst bed at various points up and down in the electric furnace.

Rate of NH <sub>3</sub> , 80 cc./min.		
Temp. of cat. C.	Eff. %	Position of catalyst bed.
830	51.91	5 cm. from lower end
835	57.52	7.5 cm.
845	70.70	Center of furnace
850	68.62	
900	77.50	5 cm. from upper end
750	74.10	
850	81.12	

These results led to the adoption of the arrangement shown in the drawing of the apparatus, whereby all the ammonia and about  $\frac{1}{2}$  of the air, after being warmed to about 80° enter the reaction tube just above the catalyst bed and are quickly swept down over the latter by the remaining air which, having passed through the furnace, was heated to about 300°.

When a very reactive catalyst was being tested no heat at all was necessary in the larger furnace; in fact it was sometimes necessary to take precautions to prevent the catalyst from melting.

## Experimental.

As has been indicated, a number of manganese alloys were made. The results of the tests of those which were examined are shown in the tables below.

TABLE V.  
ALLOY NO. 1.

Composition: Mn, 48.78%; Cu, 37.25%; Ag, 12.70%; Fe, 0.85%; SiO<sub>2</sub>, 0.50%.  
Run, 50 min. 0.5 cm. layer. Temp. of cat., 800°.

Time of contact. Sec.	NH <sub>3</sub> . Cc./min.	Air. Cc./min.	In.	HNO <sub>3</sub> . G.	Out.	Eff. %.
0.043	200	2000	25.58		15.88	62.08
0.043	200	2000	25.58		16.06	62.60
0.028	300	3000	38.52		23.18	60.20
0.028	300	3000	38.63		24.00	62.10
0.028	300	3000	38.63		24.82	64.25
0.022	400	4000	50.98		31.63	62.04
0.022	400	4000	51.36		32.50	63.20

An alloy containing a somewhat higher percentage of manganese with consequent lower percentages of copper and silver gave better yields of nitric acid. The impurities of iron and silicon were also higher. Results of test of this alloy (No. 2) are shown in Table VI.

TABLE VI.  
ALLOY NO. 2.

Composition: Mn, 59.60%; Cu, 27.40%; Ag, 8.55%; Fe, 3.25%; SiO<sub>2</sub>, 1.25%.  
Run, 50 min. 0.5 cm. layer.

Time of contact. Sec.	NH <sub>3</sub> . Cc./min.	Air. Cc./min.	In.	NHO <sub>3</sub> . G.	Out.	Temp. of cat. ° C.	Eff. %.
0.107	80	800	10.48		8.09	838	77.25
0.107	80	800	10.48		8.38	842	79.95
0.107	80	800	10.13		7.66	848	75.60

0.022	400	4000	52.03		43.72	800	84.03
0.022	400	4000	51.88		39.62	800	76.50
0.022	400	4000	52.02		44.20	800	85.13
0.022	400	4000	51.88		40.20	800	77.68
0.022	400	4000	51.50		40.88	800	79.30
0.022	450	4000	51.40		39.50	800	76.80
0.019	400	4600	58.15		44.10	800	75.80
0.019	450	4600	57.90		44.10	800	76.16
0.019	450	4600	57.76		43.66	800	75.60
0.017	500	5000	64.37		46.00	800	71.00
0.017	500	5000	61.60		46.43	800	71.90

An alloy high in manganese was made and tested to determine the limiting proportion of manganese. This alloy was not analyzed but it is believed that its composition closely approximates the proportions of the constituents which were weighed into the melt: *i. e.*, Mn, 80%; Cu, 10%; Ag, 10%.

TABLE VII.

## ALLOY No. 3.

Composition: Mn, 80%; Cu, 10%; Ag, 10%. Run, 50 min. 0.5 cm. layer. Temp. of cat., 800°.

Time of contact. Sec.	NH <sub>3</sub> . Cc./min.	Air. Cc./min.	HNO <sub>3</sub> .		Eff. %.
			In.	Out.	
0.032	200	2800	25.58	13.48	52.85
0.032	200	2800	25.49	13.45	52.80
0.027	300	3200	38.23	22.80	59.65
0.022	400	4800	50.80	23.56	46.38

It is evident from the above that the maximum manganese content lies well below 80%.

Alloy No. 4 of the following composition: Mn, 54.79%; Cu, 43.77%; Fe, 1.22%; Si, 0.09%, containing no silver at all, showed less than 25% efficiency.

Alloy No. 5 was made with the idea of duplicating No. 2. Analysis showed that it contained Mn, 56.07%; Cu, 32.81%; Ag, 9.96%; Fe, 1.23%; Si, 0.07%.

TABLE VIII.

## ALLOY No. 5.

Run, 50 min. 0.5 cm. layer.

0.027	300	3200	38.52	20.85	850	54.13

## Discussion.

As stated in the literature, manganese dioxide was found to have some effect as a catalyst for the oxidation of ammonia.

Early in this investigation it was shown that this effect can be greatly increased by the method of preparing the oxide. The physical structure of the material is of great importance, extremely fine subdivision giving a large adsorbing surface with very small pores being conducive to greater activity.

It was also shown that suitable promoters have a great influence on the catalytic activity of the material. Manganese dioxide is apparently

reduced, in the course of the reaction, to some lower oxide of manganese, and the promoter serves to aid the oxygen to reoxidize it back to the dioxide. This is indicated by the fact that when used alone, after several hours, the greater part of the manganese dioxide is reduced to the lower reddish colored oxide. That part of the material which remains black ( $\text{MnO}_2$ ) is always a thin layer on the top of the catalyst bed, being that portion which first comes into contact with the air and is consequently more readily re-oxidized. When a promoter is mixed with the manganese dioxide very little of the material shows reduction after several hours' use; in this case the reduced area (if any) is always at the bottom of the catalyst bed and is never very great.

Manganese dioxide produced by the action of methyl alcohol on potassium permanganate and, consequently consisting of comparatively coarse particles, was always less completely re-oxidized by the promoter than that prepared by the Fremy method, thus indicating qualitatively the relation of subdivision to reactivity.

When silver and copper were used together as promoters with manganese dioxide prepared by the Fremy method (Table II) there was no indication whatever of permanent reduction of the latter. This would indicate that these two materials tend to act as very efficient carriers of oxygen to the manganese.

On the other hand, however, the temperature and oxygen pressure at which the material was used was far above the dissociation temperature of silver oxide, which would lead to the conclusion that finely divided silver alone is as effective a promoter as silver oxide. This agrees with the conclusion of Lanning<sup>6</sup> drawn from his work on the carbon monoxide catalyst, in this laboratory.

The low yields of nitric acid obtained from the 3-component mixtures as shown in Table II coupled with the fact that no ammonia was detectable in the effluent gases indicates that this material (the catalyst used for carbon monoxide oxidation) is very active and that a very small time of contact is sufficient for it also to favor the decomposition of the nitric oxide once formed. This is analogous to the behavior of platinum black when used alone for this reaction. Some mixture should be possible which would be just active enough to favor the formation of nitric oxide while preventing the liberation of elementary nitrogen. Such a mixture seems to be approximated by that shown in Table III.

It was shown that alloys of manganese exist which possess considerable catalytic activity for this reaction and the data point toward an alloy of rather restricted composition which gives promise of high efficiency. Such an alloy should exist within the following limits of composition: Mn, 55-65%; Cu, 25-35%; Ag, 5-15%; Fe, 1-5%; Si, 0-3%.

<sup>6</sup> Lanning, *Dissertation, Johns Hopkins Univ.*, June, 1920.

Small changes of composition apparently have great influence on the catalytic activity and efficiency and it is believed that further investigations in this more restricted field will develop a catalyst which will yield an efficiency of 90 or 95%, or even greater.

### Summary.

Due to mechanical difficulties encountered during this investigation the above experimental data are not as extensive or complete as would be desired. It is believed, however, that the way has been cleared for a more comprehensive and exhaustive study of this subject and that in the future, such can be carried out without great difficulty.

Mixtures of especially prepared manganese dioxide containing promoters of copper and silver oxides have been made which possess great catalytic activity for the oxidation of ammonia by air.

Attention is called to the mixture of manganese dioxide and cupric oxide shown in Table III. This mixture apparently possesses as great efficiency as platinum and during the tests showed no appreciable deterioration after 6 hours continuous run.

A method is indicated for the preparation of manganese alloys relatively free from impurities. Alloys of manganese with silver and copper have been made which serve as catalysts for the oxidation of ammonia, and the approximate composition of an alloy is indicated which should give a high efficiency for this reaction.

Thanks are here expressed to Professor J. C. W. Frazer for advice and suggestions during the course of this investigation.

## THE CRYSTAL STRUCTURES OF SODIUM CHLORATE AND SODIUM BROMATE.

BY ROSCOE G. DICKINSON AND ELBRIDGE A. GOODHUE.

Received June 9, 1921.

### 1. Introduction.

Before the present research was undertaken, some X-ray work had already been done on sodium chlorate and bromate. It is mentioned in Bragg's "X-rays and Crystal Structure"<sup>1</sup> that the sodium and chlorine atoms in the chlorate are located approximately as in sodium chloride, but no data are given. Jaeger<sup>2</sup> published Laue photographs showing that the symmetry of the atomic arrangement of the chlorate is at most

<sup>1</sup> Bragg, "X-Rays and Crystal Structure," G. Belland Sons, Ltd., London, 2nd Ed., p. 173.

<sup>2</sup> Jaeger, *Verslag akad. Wetenschappen Amsterdam*, **17**, 1 (1915).

no greater than that of pyrite, but he did not attempt to deduce the structure from his results.

Since the completion of the present research in which the X-ray spectrometer was employed, a paper has appeared by Kolkmeijer, Bijvoet, and Karssen,<sup>3</sup> who studied the structures of these substances by means of powder photographs. Although their experimental method was different from ours, they arrived at the same type of structure that we had chosen; but the location of the atoms in their structure is not in full agreement with our conclusions. A comparison of their results with ours is given in a later section of this article.

This research was carried on with the aid of a grant made to Professor A. A. Noyes by the Carnegie Institution of Washington, for which we wish to express our indebtedness.

## 2. Apparatus and Procedure.

The crystals used were prepared either by slow cooling of a saturated aqueous solution in a thermostat, their formation taking place between 40° and 30°, or by the slow evaporation of a solution at room temperature. With the aid of a suitable device the desired faces were ground on the crystals using fine emery on plate glass with carbon tetrachloride as a lubricant. The accuracy of the grinding was better than 15'. Crystal faces thus prepared were set up on a holder which defined vertically the area of crystal presented to the X-ray beam. The crystal face was always chosen sufficiently long horizontally to cover the entire incident beam, even at small angles of reflection. The crystal holder was so constructed that it could be easily removed and accurately replaced on the spectrometer. In order to be able to compare intensities of reflection from various faces, a reference crystal was set up on a second holder interchangeable with the first. The crystals gave sharp reflections and were apparently good specimens.

The source of X-rays was a fine-focus Coolidge tube of the radiator type provided with a molybdenum target set in copper. The filament current was supplied by a 10-volt storage battery; the tube current was measured with a milliammeter and was kept constant with the aid of a variable resistance in the filament circuit. Except for the points mentioned the apparatus was substantially the same as that used previously.<sup>4</sup>

In the measurement of intensities an integration method similar to that described by W. H. Bragg<sup>5</sup> was employed. The ionization chamber was set on a previously measured angle of maximum reflection; then the crystal was uniformly rotated through an angular range sufficient to give sub-

<sup>3</sup> Kolkmeijer, Bijvoet and Karssen, *ibid.*, 23, 644 (1920).

<sup>5</sup> W. H. Bragg, *Phil. Mag.*, 27, 881 (1914).

stantially all of the peak in question opportunity to reflect, and the total deflection of the electroscope was read. To correct for the general radiation similar integrations were made through equal angular ranges on each side of the peak, and a mean subtracted from the deflection at the peak. The slit defining the incident beam was kept at 0.3 mm. In determining the chamber angles, the chamber slit was 0.5 mm.; but in measuring the intensities the chamber slit was opened to 1.0 mm. to avoid affecting them by any small errors in the chamber angle. In the last step measurements on the reference crystal were alternated with those on the face in question.

In order to compare intensities of reflection from different faces, it was necessary to prepare all faces by grinding in the same manner. Compton<sup>6</sup> had observed that "if the reflecting surface of a crystal of calcite is roughened by grinding, the reflection coefficient is some three times as great as from a cleavage face." With both sodium chlorate and sodium bromate it was found that with natural faces that had not been cleaved there was a similar effect, and that the increase in intensity on grinding, amounting in some cases to over 100%, was greater the smaller the angle of reflection. By turning the crystal face through 180°, as recommended by W. H. Bragg,<sup>5</sup> the effect was shown not to be due to inaccurate grinding. W. L. Bragg, James, and Bosanquet<sup>7</sup> have recently observed the same phenomenon with sodium chloride, using first a cleavage surface. The occurrence of this effect, which is still under investigation in this laboratory, is the rule rather than the exception and seems to indicate that all naturally grown faces, as well as cleavage faces of crystals, are covered by a thin absorbing, but non-reflecting layer.

Another important precaution was found necessary in the present measurements. It is, perhaps, best shown by means of an example. A large (110) face of sodium chlorate was set up not limited vertically by one of the holders described above; the crystal was set with two cube faces vertical and with the other four making angles of 45° with a horizontal plane. The chamber and crystal angles for two reflections were found; with the aid of these, the angles of reflection in the entire region between chamber angles of 2° and 33° were measured, rotating the crystal half as fast as the chamber. In this manner peaks were found at chamber angles of 9° 10', 13° 40', 18° 0', and 27° 0'. If each of these is divided by two and a correction of 11' subtracted from each of the results, the glancing angles 4° 24', 6° 39', 8° 49', and 13° 19' are obtained. These seemed to be the angles of reflection for the second, third, fourth and sixth orders, respectively, consistent with the fundamental equation  $n \lambda = 2d \sin \theta$ ; for on dividing the sines of these angles by 2, 3, 4, and 6, re-

<sup>6</sup> A. H. Compton, *Phys. Rev.*, 10, 95 (1917).

<sup>7</sup> W. L. Bragg, James, and Bosanquet, *Phil. Mag.*, 41, 316 (1921).

spectively, the numbers 0.0384, 0.0386, 0.0384, 0.0384 are obtained. Yet, if the crystal and slits have moderately large vertical dimensions, reflections from a number of atom planes with different indices, but from the same boundary of the crystal, may enter the ionization chamber; moreover, it can be shown analytically that when the crystal is set with an important zone axis horizontal, as in the above case, these reflections, although coming from planes whose spacings are irrationally related to those of the prepared face, may have crystal and chamber angles very nearly in accord with the sine law and thus appear to come from the prepared face. That this had taken place in the case of the (110) spectra was clearly shown photographically. A photographic plate was set up perpendicularly to the incident beam, and in place of the ionization chamber. The crystal (set up as above) was rotated slowly and uniformly through a region sufficient to include the above lines. The reflections which had been called the 2nd, 4th, and 6th orders appeared as a horizontal row of vertical lines. The reflection which had been called the third order showed as a strong vertical line, which was not, however, in a horizontal row with the others. Another strong line was found directly below and partly overlapping the 2nd order. These last two clearly did not belong to the (110) spectra. Other lines from other faces were also in evidence. If this interpretation is correct, it should follow that when the crystal is moved in such a way that (110) remains vertical but the other faces are rotated, and a photograph taken as before, the real reflections from (110) should persist, but those from other faces undergo alteration. A photograph was made in the same manner as the previous one, but with two cube faces horizontal and four vertical. The lines previously called the 2nd, 4th, and 6th orders were the only ones common to the two photographs. By limiting the crystal face vertically to about 5 mm. by means of the holder, and by setting the crystal with no important zone axis horizontal, it was found possible to isolate these three lines for intensity measurement. Similar precautions were taken in the measurements on other faces. It seems likely that failure to observe this precaution is responsible for confusion that has arisen in the literature and that it accounts for cases where one investigator has reported reflections which the other did not find.

### 3. The Experimental Data.

An extended series of observations on sodium chlorate and a few on sodium bromate are given in Tables I and II. Since faces of the form (hok) are geometrically indistinguishable from those of the form (ohk) until the directions of the axes have been chosen, the faces (201), (10 $\bar{2}$ ), (301) and (10 $\bar{3}$ ) were all cut from the same crystal. The same is true of the two faces (111) and ( $\bar{1}\bar{1}\bar{1}$ ). The tabulated values are, in many cases, means of several determinations.

#### 4. Derivation of the Crystal Structures.

The type of atomic arrangement in these substances is probably most conveniently arrived at by a method which has been described by Wyckoff,<sup>8</sup> to whom we are also much indebted for personal explanations of the application of the theory of space groups. It is always possible to regard a cubic crystal as built up by the repetition of a unit of structure on a simple cubic lattice; and we can determine the number *m* of molecules (of NaClO<sub>3</sub> or NaBrO<sub>3</sub>) in the unit of structure by means of the equation

<sup>8</sup> Wyckoff, *Am. J. Sci.*, 1, 127, 138 (1920).

$\frac{n^3}{m} = \left( \frac{2 \sin \theta}{\lambda} \right)^3 \frac{M}{N\rho}$ . In this equation  $n$  denotes the order of reflection (based on the simple cubic lattice);  $\lambda$ , the wave length<sup>9</sup> of the X-rays used ( $0.710 \times 10^{-8}$ );  $\theta$ , the angle of reflection from a cube face;  $\rho$ , the density of the crystal;  $M$  the formula-weight of sodium chlorate (or bromate), and  $N$  Avogadro's number ( $6.06 \times 10^{23}$ ). The density has been taken as 2.49 for the chlorate and 3.30 for the bromate.<sup>10</sup> Taking for  $\theta$  the smallest angle at which reflection was found from the cube face with each substance, and substituting the proper values of the other quantities, we get  $n^3/m$  equal to 1.99 for the chlorate and 2.00 for the bromate. If  $n = 2$  and  $m = 4$ ,  $n^3/m$  is 2; and these are the only possible values of  $n$  and  $m$  that bring  $n^3/m$  into close agreement with the values calculated above. For, if the structure be assumed to contain only one kind of sodium atom and one kind of chlorine (or bromine) atom, and not more than three kinds of oxygen atoms, the value of  $m$  can only be 48 or a submultiple of 48; for there are 12 equivalent directions in the cubic tetartohedral point-group, and there may be 1, 2, or 4 lattice points associated with the unit of structure. This shows that the crystal structure may be obtained by the repetition of a unit containing 4  $\text{NaClO}_3$  (or 4  $\text{NaBrO}_3$ ) on a simple cubic lattice.

The dimensions of the lattices can probably be most accurately obtained from the densities. Thus, the length  $d_{100}$  of the side of the unit cube may be calculated by the equation,

$$d_{100} = \left( \frac{4M}{N\rho} \right)^{1/3}$$

This gives for sodium chlorate  $6.56 \times 10^{-8}$  cm., and for sodium bromate  $6.71 \times 10^{-8}$  cm.

The angles at which reflection should occur from any other face having the Miller indices ( $h \ k \ l$ ) may now be calculated with the aid of the expression

$$n \lambda = \frac{2 d_{100} \sin \theta}{\sqrt{h^2 + k^2 + l^2}}$$

With the omission of the odd orders from the cube faces, the angles so calculated are given in Tables I and II along with the observed angles.

The assumption is made that all of the oxygen atoms occupy equivalent positions in the structure, it is next necessary to consider among the cubic tetartohedral space groups those which give in the most general or in special cases 4, 4, and 12 equivalent positions per unit of structure. There are two space groups which accomplish this, namely, those designated by Schönflies<sup>11</sup>  $T^1$  and  $T^4$ .

<sup>9</sup> See Duane, *Nat. Research Council Bull.*, 1, part 6 (1920).

<sup>10</sup> Groth, "Chemische Krystallographie," Wilhelm Engelmann, Leipzig, 1908, vol. 2, p. 84.

<sup>11</sup> Schönflies, "Krystallsysteme u. Krystalstruktur," Teubner, Leipzig, 1891.

The arrangement of atoms is, according to  $T^1$ ,

The parameters appearing in the coördinates are taken as fractions of  $d_{100}$ . Since the right- and left-handed varieties of a crystal behave in the same manner toward X-rays,<sup>2</sup> it is not possible to choose between two enantiomorphously related structures.

The arrangement of atoms is, according to  $T^4$ ,

No odd orders of reflection were found from the cube faces of either of the substances. Now irrespective of the values of  $u$ ,  $v$ ,  $x$ ,  $y$ , and  $z$ , and of any special assumptions as to the reflecting power of the different atoms, the second arrangement, but not the first, causes all the odd orders of reflection from the cube faces to vanish.

The assumption here made that all the oxygen atoms occupy equivalent positions seems justifiable. For no arrangement with the requisite symmetry and number of sodium chlorate per unit is possible on the assumption that two oxygen atoms are equivalent and the third different; and the assumption that all three oxygen atoms are non-equivalent is improbable. We have therefore adopted the arrangement derived from the space group  $T^4$ .

Completion of the knowledge of the crystal structure requires the determination of the values of the 5 unknown parameters, and this can best be done by a consideration of the intensities of reflection. There seems to be no way of finding the values of these parameters except by trial; and since 5 of them are involved, the number of possibilities is great. In view of the present rather scant knowledge of the mechanism of reflection there is no way of knowing how good agreement to expect between the calculated and observed results. There is, moreover, no assurance that when a satisfactory set of values has been found, another equally good set may not be possible. We have nevertheless determined a set of values of these parameters which leads to a rough agreement between the calculated and observed intensities.

The intensities were calculated with the aid of the expression,  $I = f(\theta)(A^2 + B^2)$ . In this expression,

$$\begin{aligned}
A = & \bar{\text{Na}} \left[ \cos 2\pi n(h+k+l)u + \cos 2\pi n\left(\frac{h+k}{2} + (h-k-l)u\right) \right. \\
& \left. + \cos 2\pi n\left(\frac{k+l}{2} + (-h+k-l)u\right) + \cos 2\pi n\left(\frac{h+l}{2} + (-h-k+l)u\right) \right] \\
& + \bar{\text{Cl}} \left[ \cos 2\pi n(h+k+l)v + \cos 2\pi n\left(\frac{h+k}{2} + (h-k-l)v\right) \right. \\
& \left. + \cos 2\pi n\left(\frac{k+l}{2} + (-h+k-l)v\right) + \cos 2\pi n\left(\frac{h+l}{2} + (-h-k+l)v\right) \right] \\
& + \bar{\text{O}} \left[ \cos 2\pi n(hx+ky+lz) + \cos 2\pi n\left(\frac{h+k}{2} + hx-ky-lz\right) \right. \\
& + \cos 2\pi n\left(\frac{k+l}{2} - hx+ky-lz\right) + \cos 2\pi n\left(\frac{h+l}{2} - hx-ky+lz\right) \\
& + \cos 2\pi n(hz+kx+ly) + \cos 2\pi n\left(\frac{k+l}{2} - hz+kx-ly\right) \\
& + \cos 2\pi n\left(\frac{h+l}{2} - hz-kx+ly\right) + \cos 2\pi n\left(\frac{h+k}{2} + hz-kx-ly\right) \\
& + \cos 2\pi n(hy+kz+lx) + \cos 2\pi n\left(\frac{h+k}{2} - hy-kz-lx\right) \\
& \left. + \cos 2\pi n\left(\frac{h+k}{2} + hy-kz-lx\right) + \cos 2\pi n\left(\frac{k+l}{2} - hy+kz-lx\right) \right]
\end{aligned}$$

Fig. 1

B is a similar expression in sine terms. Here Na, Cl, and O have been taken proportional to the atomic numbers of the respective elements. The relative values of  $f(\theta)$  have been estimated by taking 100:20:5 as the normal ratios for the cube face of sodium chloride, plotting these against  $\sin \theta$ , and drawing an interpolation curve through these points. In order to get a straighter curve, the plot was actually made with the reciprocals of the square roots of the normal intensities against  $\sin \theta$ .

Tables III and IV contain the results of these calculations. The values of the parameters finally chosen are for the chlorate,  $u = 0.08$ ,  $v = 0.43$ ,  $x = 0.30$ ,  $y = 0.59$ ,  $z = 0.47$ ; for the bromate;  $u = 0.09$ ,  $v = 0.41$ ,  $x = 0.30$ ,  $y = 0.60$ ,  $z = 0.47$ . The tables show in the fourth column the observed intensities; in the fifth, the intensities calculated using our values of the parameters; in the sixth, the intensities calculated using the parameters  $u = \frac{5}{12} = (0.083)$ ,  $v = \frac{5}{12} = (0.417)$ ,  $x = \frac{1}{2} = (0.500)$ ,  $y = \frac{5}{12} = (0.417)$ ,  $z = \frac{11}{36} = (0.306)$ , which are those chosen by Kolkmeijer, Bijvoet and Karssen.<sup>3</sup> These three sets of intensities are also shown graphically in Fig. 1. The heavy lines represent the observed intensities. The lighter lines to the left represent the intensities calculated with our parameters, while the light lines to the right represent the intensities calculated with the parameters of Kolkmeijer, Bijvoet and Karssen. Their structure gives as good agreement with our data as our own structure except for faces all of whose indices are different. That any disagreement should appear here, if at all, is not surprising, since powder photographs, from which their structure was derived, do not separate reflections due to (hkl) and (khl).

## 5. Discussion of the Crystal Structures.

Their structure and ours are in substantial agreement as regards the displacement of the sodium and halogen atoms toward each other along diagonals from the positions occupied by these atoms in the sodium halides; and both agree in placing 3 oxygen atoms near a halogen with the halogen nearly in their plane. But their structure orients the oxygen atoms somewhat differently from ours and places them considerably closer to the halogen. Thus the distances between the respective atoms corresponding to their parameters and ours are shown in Table V.

In the last column are shown the distances derived by Bragg's contact-sphere

● Sodium, ○ Halogen; ○ Oxygen

Fig. 2.

principle using his values for the atomic radii.<sup>12</sup> As already pointed out by Kolkmeijer, Bijvoet, and Karssen, their values for the distances between halogen and oxygen are much less than those to which Bragg's atomic radii lead. The difference is seen to be much less in the case of our values, which for the chlorate were deduced before Bragg's paper appeared.

<sup>12</sup> W. L. Bragg, *Phil. Mag.*, 40, 180 (1920).

The arrangement of the atoms in the unit of structure using our chlorate parameters is shown in Fig. 2.

### Summary.

1. Considerable X-ray spectrometer data for sodium chlorate and a smaller amount for sodium bromate have been collected and tabulated.
2. In agreement with other observers, it has been found that the nature of the crystal surface has a considerable effect on both the absolute and relative intensities of reflection.
3. The ease with which reflections from one face may be mistaken for those from another, and the necessity of precautions to avoid this have been pointed out.
4. It has been shown that the atoms in sodium chlorate and sodium bromate are very probably arranged with the symmetry of the space-group  $T^4$ , all oxygen atoms being equivalent.
5. Sets of locations of the atoms in the unit of structure, only slightly different for the chlorate and bromate, have been suggested.

## CATALYSIS IN THE INTERACTION OF CARBON WITH STEAM AND WITH CARBON DIOXIDE.

BY HUGH STOTT TAYLOR AND HARVEY A. NEVILLE.

Received June 20, 1921.

### Introduction.

The interaction of carbon and steam yields, in the first stage of the process, carbon monoxide and hydrogen, according to the equation

In presence of an excess of steam, and especially with suitable catalytic agents, the primary stage may be succeeded by the following reaction.

The first equation represents the desired reaction in the steaming phase of blue water-gas preparation. The second occurs to a certain extent, especially as the temperature of the fuel bed is lowered, the ash content of the coke acting as catalytic agent.<sup>1</sup> In the absence of catalytic agents as, for example, with carbon obtained by the thermal decomposition of hydrocarbons, and therefore ash-free, the first reaction takes place practically exclusively. It is evidently, therefore, a faster reaction than the water-gas reaction in the absence of catalytic agents. The second reaction is the principal reaction in the catalytic process for the manufacture of hydrogen from water-gas and steam. Iron oxide is an important con-

<sup>1</sup> Gwosdz, *Z. angew. Chem.*, 31, 137 (1918).

stituent of catalytic agents preferred technically in this process. Since the equation for the water-gas reaction represents an equilibrium which is exothermic in the direction of hydrogen production, it follows that low temperatures and excess of steam favor the elimination of carbon monoxide from the products of the reaction. Temperatures in the neighborhood of 500° are therefore employed in the production of hydrogen by the water-gas catalytic process.

Various attempts have been made to conduct these two reactions in a one-stage technical operation whereby steam is to be passed over carbon of suitable form at a low temperature, so that the reaction products are, in the main, carbon dioxide and hydrogen. To do this efficiently it is necessary to increase the activity of carbon toward steam by the addition of suitable catalytic agents to the reaction mass.

There are a number of patents in existence covering the use of various materials which are to be mixed with charcoal or coke in order to lower the temperature at which the reaction takes place and increase the hydrogen production when the mixture is treated with steam. Among the earliest of these patents is one dated 1867,<sup>2</sup> which proposes the production of hydrogen and carbon dioxide by passing steam over fuel impregnated with lime or caustic soda and heated. Krupp,<sup>3</sup> in a patent of 1892, specifies fuels mixed with hydrates or carbonates. The formation of carbon monoxide is minimized and the carbon dioxide produced is removed by passing over lime. Dieffenbach and Moldenhauer<sup>4</sup> in a series of patents of 1910 suggest the use of coke impregnated or admixed with chlorides, sulfates, or sulfides. Such preparations are stated to be sufficiently active at 600°. With a silicate as catalyst a temperature as high as 750° is used. One of the patents recommends pulverizing the materials, mixing intimately, and briquetting the powdered mixture. It is here claimed that the concentration of carbon monoxide does not exceed a few tenths of 1% when operating at the low temperatures stated. Another patent<sup>5</sup> recommends the admixture of lime in addition to the catalytic agent, in order to absorb the carbon dioxide as it is produced, and thus lower still further the carbon monoxide concentration. A particular preparation mentioned consists of coke impregnated with a 10% potassium carbonate solution and mixed with 5 times its weight of lime, the interval of the reaction temperature being 550–750°. The formation of calcium carbonate is of advantage as the reaction is strongly exothermic and the net thermal effect is therefore positive.

<sup>2</sup> Tessie du Motay and Marechal, Brit. pat. 2548, 1867.

<sup>3</sup> Krupp, Brit. pat. 8426, 1892.

<sup>4</sup> Dieffenbach and Moldenhauer, Brit. pat. 7718, 7719, 7720, 1910.

<sup>5</sup> Dieffenbach and Moldenhauer, Brit. pat. 8734, 1910.

For this reason the duration of steam passage for a given temperature of fuel-bed could be increased.

According to the most recent data,<sup>6</sup> the dissociation pressure of calcium carbonate at 750° is 68 mm. Since the partial pressure of carbon dioxide in the gaseous product would be one-third of an atmosphere, or 253 mm., (assuming the process conducted at atmospheric pressure) if all the steam were converted to hydrogen and carbon dioxide, the lime would, in this case, remove 73% of the carbon dioxide present in the issuing gas. However, there is always an excess of steam, and the partial pressure of carbon dioxide is always less than 253 mm., and hence a smaller percentage is always removed. When the partial pressure of the carbon dioxide falls to 68 mm., none is removed. This will be the case when about 4 times as much steam as will react is being used or, in other words, when a 25% conversion of steam to hydrogen is being obtained. It is thus apparent that the use of lime for the purpose stated cannot be of considerable consequence, unless temperatures in the neighborhood of 550° are used. Since the dissociation pressure of calcium carbonate is only 0.57 mm. at this temperature, a 99% absorption would be attained with a 25% conversion efficiency.

In another list of patents, steam and carbon monoxide, or gases containing it, are passed over coke mixed with metallic oxides and alkalis.<sup>7</sup> Catalysts consisting of metallic couples,<sup>8</sup> such as copper-iron, are also mentioned. Increased pressure is advocated in some cases. For instance, it is stated<sup>9</sup> that, with the use of lime and charcoal, almost pure hydrogen is produced by using steam at ten atmospheres pressure.

Prins,<sup>10</sup> in a patent of 1917, has stated in a more general way the catalysts to be employed in the reaction of steam on carbon. Two or more catalytic agents are to be chosen, one or more from each of the following groups: (a) oxygen-containing salts of the alkali or alkaline-earth metals; (b) inorganic oxides or hydroxides which behave as non-volatile, weak acids or acid anhydrides, as, for example, boric oxide, aluminum oxide, silicon dioxide. Oxides of iron, chromium, and manganese may also be incorporated, doubtless for the purpose of promoting the water-gas reaction which is the second stage of the process, as was previously pointed out. The specified temperature varies from 300° to 600°. The following mixture, for instance, is stated to be efficient at 400–500°: tricalcium orthophosphate, 1 part; silicon dioxide, 2 parts; coke, 20 parts.

It is apparent that there is in the foregoing statements no information

which would indicate the relative merits of the proposed catalysts, the optimum concentration of these, or the effect of temperature change upon the reactions. Neither is there any suggestion of the nature of the mechanism of the catalysis. It was therefore decided in this research to gain some knowledge upon these points by a systematic study of various catalytic agents in their influence upon the reactions. This study has led to a wholly unexpected development of the program of work, since the mechanism of the acceleration by catalytic agents is quite other than was anticipated at the outset.

Many agents were found to catalyze the steam-carbon reaction of which the best were the carbonates of potassium and sodium. With the idea that their influence was to be ascribed to an acceleration of the water-gas reaction,  $\text{CO} + \text{H}_2\text{O} = \text{CO}_2 + \text{H}_2$ , this being known to be slower than the steam-carbon reaction in the absence of catalysts; known good catalysts for the water-gas reaction, for example, iron oxide, were tried as catalysts for the steam-carbon reaction. Iron oxide was found to be quite inactive in this respect, and it was evident, therefore, that another explanation of the mechanism must be sought.

As a possible explanation of the observed catalytic effect in the steam-carbon reaction, it occurred to us that the interaction of carbon dioxide and carbon might be facilitated by the catalytic agents in question and that this was the key to the mechanism of the former reaction. For, if such were the case, the carbon dioxide produced in the second stage of the steaming process,  $\text{CO} + \text{H}_2\text{O} = \text{CO}_2 + \text{H}_2$ , would then interact with carbon to form monoxide,  $\text{CO}_2 + \text{C} = 2\text{CO}$ , which gas, in the presence of the excess of steam, would react as above to form additional quantities of carbon dioxide and hydrogen, thus increasing the net yield of gas from the steam reaction. Experimental tests of this idea showed a complete parallelism between the catalytic effects in the two reactions. In this case reduced nickel was the only catalyst found by us to be superior to the alkali carbonates as accelerating agent, and investigation showed that the low activity of nickel in the steam-carbon reaction was due to a condition brought about by a side reaction, as will be described later. Poor catalysts in the steam-carbon reaction were found to be poor catalysts in the carbon dioxide-carbon reaction, and no material would catalyze this reaction which was not also active in the former case.

As an explanation of the catalytic effect in the carbon dioxide-carbon reaction, it was shown that a mechanism involving alternate reduction and reformation of the alkali carbonates was not correct. These experiments, however, led us to make a determination of the adsorption capacity of carbon for carbon dioxide at the reaction temperatures concerned, both when alone and when impregnated with various catalytic agents. The results of these experiments showed in a striking manner that good catalysts

for both of the reactions under investigation also caused a marked increase in the adsorptive capacity of carbon for carbon dioxide as measured at 445°. Our experiments have indicated that this increased adsorption of carbon dioxide by carbon may be attributed to the action of the catalytic agents in facilitating the decomposition of "fixed oxygen" complexes on the carbon surface, thus cleaning the surface to an extent which would ordinarily only be attained by subjecting the carbon to considerably higher temperatures.<sup>11</sup> Definite evidence has also been obtained that such inactive oxygen complexes may be partially broken down into carbon monoxide and carbon dioxide by prolonged heating at the temperature of the experiments, even in absence of catalytic agents, and that they may be reformed by carbon dioxide under these conditions.

## II. Experimental.

**Materials.**—The form of carbon most extensively studied in this investigation was a coconut-shell charcoal produced in large quantities during the recent war for use in gas masks, and officially known as A909. This charcoal was prepared from coconut shells by carbonization at 950° for 10 hours, followed by steam activation at 950° for 45 minutes.<sup>12</sup> The sample used was passed through an 18-mesh screen and the finer powder removed. The true density of this charcoal was found to be 1.84.<sup>13</sup>

Other forms of carbon used were: (1) sugar charcoal, made by dehydrating recrystallized cane sugar with conc. sulfuric acid, subsequent washing free from acid and heating to dull redness; (2) a high-temperature coke; (3) kelp-char, containing 2.2% of alkali carbonates, calculated as sodium carbonate, which could be extracted with hot water; (4) a retort carbon furnished by the DuPont Company, containing 1.8% of sodium carbonate, determined as above.

The catalysts employed, in the case of salts, were the pure anhydrous compounds. A charge was prepared as follows. The carbon and the catalyst in weighed proportions were moistened with water, mixed thoroughly, and then heated until dry. In this way the catalyst was deposited on the surface and in the pores of the charcoal in a finely divided form, and in intimate contact with the carbon. When reduced nickel was used as catalyst, the desired amount was weighed out as tetrahydrated nickel nitrate ( $\text{Ni}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ ), dissolved in water and the charcoal moistened with the solution. This mixture was then dried and heated to decompose the nitrate, leaving the oxide of nickel on the surface of the charcoal. The sample was then placed in the reaction tube and reduced *in situ* with hydrogen at the temperature at which it was to be used, that is, 570°. A charge consisted of 8 g. of charcoal plus an amount of the catalyst calculated as a certain percentage of the total weight. For example, A909 plus 20% of potassium carbonate refers to 8 g. of the char mixed with 2 g. of anhydrous potassium carbonate.

**Apparatus.**—The apparatus used to study the reaction of steam upon carbon was essentially as shown in Fig. 1. It was constructed entirely of Pyrex glass. The internal diameter of the reaction tube was 1.6 cm., and the charge occupied a length of 11 cm. The thermocouple in its sheath was inserted so that its end was at the middle point of the charge. It was made of Hoskins base metal alloys (No. 183 vs. 343; 343 pos.) and was calibrated at several points between 100° and 658°. The temperature was measured

<sup>11</sup> Lowry and Hulett, *THIS JOURNAL*, 42, 1408 (1920).

<sup>12</sup> Lamb, Wilson and Chaney, *J. Ind. Eng. Chem.*, 11, 420 (1919).

by means of a pyrovoltmeter made by the Pyroelectric Company, the accuracy being well within  $\pm 5^\circ$  and the relative variations probably much less. The two joints of the apparatus were made securely gas-tight by wrapping them with rubber dam. The portion of the apparatus extending out of the furnace was wound with resistance wire

Fig. 1.—Diagram of apparatus.

and heated to prevent condensation of the steam. This steam was generated electrically as shown in the figure. A current of steam was passed through the outer jacket of this generator in order to bring the contents to  $100^\circ$ . Inside, was a platinum spiral of known resistance with leads fused through the glass. This was heated by a constant direct

Fig. 2.—Amount of gas produced with different percentages of sodium carbonate.

current to convert the water at 100° to steam. The rate of steam passage per minute could be calculated from the relation

$$H = 0.24 I^2 R t = 64.08 \text{ calories,}$$

where  $H$  is the number of calories of heat produced;  $I$ , the current (1 ampere);  $R$ , the resistance of the spiral at 100° (4.45 ohms);  $t$ , the time (60 seconds); and 0.24, the heat equivalent of electrical energy. The heat of vaporization of water at 100° is 538 cal.;  $64.08/538 = 0.1191$  g. of water vaporized per minute, which corresponds to 148 cc. at 0° and 760 mm. pressure, and to 160 cc. at 20° and 760 mm.

Fig. 3.—Amount of gas produced with different percentages of potassium carbonate.

In studying the reaction of carbon dioxide upon the charcoal, a reaction tube similar to the one shown in Fig. 1 was used, with the exception that the steam generator was replaced by a side tube through which carbon dioxide was introduced. The carbon dioxide was obtained from a tank of the liquefied gas. Its rate of passage was measured by a flow-meter which had been previously calibrated for this gas. A constant pressure of carbon dioxide through the system was maintained by means of a blow-off through a side tube extending into an adjustable height of water. The gases issuing from this reaction were collected over caustic potash solution in order to absorb the carbon dioxide which had not been reduced. The residual gas was practically pure carbon monoxide, containing a small amount of hydrogen, due either to a trace of moisture in the carbon dioxide or in the charcoal, or obtained by further decomposition of hydrocarbons not removed from the char in its preparation.

### III. Experimental Results.

**Steam on Carbon.**—The temperatures chosen for this study were conveniently 490°, 525° and 570°. Below 490° the reaction was too slight to be appreciable in most cases, and above 570° the reaction tube softened.

As a basis for comparison, an experiment was carried out without any catalyst. This was followed by experiments on charcoal moistened with solutions of barium hydroxide, water glass, borax, soda-lime, sodium and potassium carbonates. The last two substances, only, showed a considerable catalytic effect. These two alkali carbonates were subsequently studied as catalysts in detail, in addition to a number of other substances.

Fig. 4.—Comparison of K<sub>2</sub>CO<sub>3</sub> and Na<sub>2</sub>CO<sub>3</sub>. Reaction  
 $C + 2H_2O = CO_2 + 2H_2$ .

The results are shown in the accompanying Table I. The data on sodium and potassium carbonates are graphically represented in Figs. 2, 3, 4 and 5. The effect upon the reaction of variations in the temperature and in the amount of catalytic agent employed is clearly indicated in these curves. The results here recorded were obtained by passing steam at a constant rate of 160 cc. per minute over 8 g. of charcoal plus the catalyst, prepared as described above. The rate of production of gas was measured in cubic centimeters per minute at 20° and 760 mm. pressure, and was taken

as an indication of the relative rate of the reaction in each case. The gases were collected over dil. sulfuric acid and were completely analyzed. Their composition usually approximated a mixture of two volumes of hydrogen and one volume of carbon dioxide, in agreement with the relation  $C + 2H_2O = CO_2 + 2H_2$ . When there was a deviation from this ratio it could be explained. For example, when using lithium, calcium or barium carbonate as catalyst, the proportion of carbon dioxide was too great, owing to dissociation of the carbonate. When an oxidizing agent like sodium nitrate was used, too much carbon dioxide was found in the

Fig. 5.—Concentration of catalyst in percentages.

product because oxidation of the carbon or removal of hydrogen by oxidation had occurred. In this instance, some oxygen also was found.

The presence of carbon monoxide in the reaction product could hardly ever be detected with our gas-analysis apparatus, as the amount present in a 20cc. sample was usually less than 0.05 cc. The theoretical concentration of carbon monoxide at any temperature can be calculated from the water-gas equilibrium,  $CO + H_2O \rightleftharpoons CO_2 + H_2$ .

At equilibrium,

$$\frac{C_{H_2O} \times C_{CO}}{C_{H_2} \times C_{CO_2}} = K = 0.25 \text{ at } 600^\circ.$$

With steam passing at the rate of 160 cc. per minute, and gas being produced at the rate of 6 cc. per minute, taking into account the fact that  $\frac{2}{3}$  cc. of steam disappears for every cubic centimeter of gas produced, the equation becomes

$$\frac{155.3 \times C_{\text{Co}}}{4 \times 2} = 0.25.$$

Hence the production of carbon monoxide is at the rate of 0.013 cc. per minute, which represents 0.21% of the gas mixture. When gas is produced at the rate of 25 cc. per minute (cf. A909 + 20%  $\text{K}_2\text{CO}_3$ ) the quantity of carbon monoxide becomes 0.24 cc. per minute or 0.96% of the gaseous product.

The data recorded in Table I make apparent the following facts. (1) Of the materials studied, potassium and sodium carbonates are the only efficient catalysts for the reaction, and potassium carbonate is about three times as active in this respect as the sodium salt. (2) Other salts of the alkalies and alkaline earths have a slight catalytic effect. (3) Iron oxide exerts no influence whatever.

Since it is almost certain that the reaction progresses in two stages, (a)  $C + H_2O = CO + H_2$ ; (b)  $CO + H_2O = CO_2 + H_2$ ;  $C + 2H_2O = CO_2 + 2H_2$ , and since iron oxide is a very good catalyst for Reaction b, it may be concluded that first, the water-gas reaction attains its equilibrium under the conditions of these experiments, even in the absence of such substances as iron oxide; and second, the observed catalysis of the reaction between steam and carbon cannot be due to a catalysis of the water-gas reaction but must be due to an acceleration of the first stage or of some other reaction concerned. The catalysis of the reaction,  $C + CO_2 = 2CO$ , satisfies these conditions and is considered sufficient to account for the increased production of gas when catalytic agents are used in the steam-carbon process.

Fig. 6.—Rate of  $CO_2$ . Cc. per min.

Charcoal, containing reduced nickel incorporated in the manner previously described, when treated with steam at  $570^\circ$ , produced gas at the rate of 80 cc. per minute at the beginning of the operation. After an hour's passage of steam, the rate of evolution of gas had fallen to 6 cc. per minute. It was thought that the decrease in the activity of the nickel as catalyst might be due to surface oxidation by the steam. If this were the case, it should recover its activity when again reduced with hydrogen. The steam generation was stopped and a stream of hydrogen was substituted for it. When steam was again passed through the charge, the evolution of gas was at the rate of 4 cc. per minute, and fell during an hour to an

apparently constant value at 2.6 cc. per minute. It is probable that the nickel had either become coated over with a deposit of carbon due to decomposition of carbon monoxide, a reaction catalyzed by nickel, or that it had been agglomerated, by being heated at  $570^{\circ}$  for a considerable time, into larger particles which had much less catalytic activity.

**Carbon Dioxide on Carbon.**—Materials similar to those studied in the preceding steam-carbon reaction were used as catalysts for this reaction. The results of these experiments are recorded in Table II and graphically represented in Fig. 6. From a comparison of the values given in the two tables, it is evident that the activities of the catalytic agents are in the same order in the two reactions. These experiments were all carried out at  $570^{\circ}$ , but the rate of passage of carbon dioxide was varied. An excess of an inactive catalyst such as calcium carbonate mixed with the charcoal produced a more decided protective effect than was observed in the steam-carbon reaction. In the latter case, the velocity of the gas (160 cc. per minute) through the apparatus was from 5 to 20 times as great and, therefore, the turbulent motion of its molecules was less impaired than in the case of the slower stream of carbon dioxide. The two experiments with nickel as catalyst, using respectively 7.5 and 20% of the metal, gave almost identical results, indicating that the optimum concentration of catalytic agent was already reached in the first instance.

The decomposition of carbon monoxide into carbon dioxide and carbon, as was mentioned earlier, was known to be catalyzed by reduced nickel. It was, therefore, to be expected that nickel would catalyze the reverse reaction,  $\text{C} + \text{CO}_2 = 2\text{CO}$ . Reference to Table II will show that it was by far the best catalyst found. Furthermore, it did not lose its activity as it did in the steam-carbon reaction. The large excess of carbon dioxide in the present instance, no doubt, prevented the reverse reaction from being considerable.

It was supposed by H. St.-Claire Deville, who first observed the decomposition of carbon monoxide, that the decomposition would increase with rise in temperature.<sup>14</sup> However, since the reaction is exothermic,  $2 \text{ CO} = \text{CO}_2 + \text{C} + 39 \text{ kg. cal.}$ , according to the van't Hoff principle of mobile equilibrium, the quantity of carbon monoxide present in equilibrium with carbon dioxide and carbon will decrease as the temperature is lowered. Boudouard's results<sup>15</sup> for this equilibrium are, 0, 39.0 and 93.4% of carbon monoxide remaining at 445°, 650° and 800° respectively. Rhead and Wheeler<sup>16</sup> found figures substantially in agreement with Boudouard at the higher temperatures by heating carbon in an atmosphere of carbon dioxide, namely 93.77 and 97.78% of carbon monoxide formed at 850° and 900°, respectively. They also noted that the reaction  $\text{C} + \text{CO}_2 = 2 \text{ CO}$ , proceeded 166 times as fast as the reverse reaction at 850°.

Following Boudouard's conclusion that carbon monoxide is metastable at 445°, Smits and Wolff undertook to determine the velocity of the decomposition,  $2 \text{ CO} = \text{CO}_2 + \text{C}$ , in the metastable range, using finely divided nickel as catalyst.<sup>17</sup> They found the reaction to be monomolecular, and assumed that it occurred in two phases: (1)  $\text{CO} = \text{C} + \text{O}$ , with measurable velocity; and (2)  $\text{CO} + \text{O} = \text{CO}_2$  with immeasurably great velocity. They determined that the reaction, in contradiction to the work of Boudouard, was very distinctly reversible at 445°, but found no satisfactory value for the equilibrium constant. The incompleteness of decomposition of carbon monoxide at 445°, as indicated in this research is of importance in reference to the value of 23.15% of carbon monoxide obtained by us in the experiment cited below. These values suggest the necessity of a careful restudy of the equilibrium,  $\text{CO}_2 + \text{C} \rightleftharpoons 2 \text{ CO}$ , in the interval 445–800°.

Briner and Wroczynski<sup>18</sup> found that, in agreement with the Le Chatelier theorem, the decomposition of carbon monoxide was favored by increased pressure. Rhead and Wheeler corroborate this in a later paper,<sup>19</sup> and apply a formula to calculate the ratio  $\text{CO}/\text{CO}_2$  at any temperature and pressure:

$$\frac{38055 + 2.02 T - 0.0031 T^2}{2 T} + \ln P + \ln \frac{C_1}{C_2} = K = 18.75.$$

In the present investigation, when carbon dioxide was passed at a very slow rate over carbon coated with 7.5% reduced nickel at 570°, the resulting gas, collected over mercury and analyzed, was found to contain 23.15%

of carbon monoxide. This was the average of 6 analyses which were in close agreement among themselves. As calculated by means of the above formula, the pressure being one atmosphere and, therefore, the middle term dropping out, the concentration of carbon monoxide at 570° should be 17.3%.

Upon the principle that the catalyst for a reaction should also catalyze the reverse reaction, it was attempted to show that potassium carbonate would accelerate the decomposition of carbon monoxide. A stream of carbon monoxide which had been purified and dried was passed at a constant rate of 10 cc. per minute over a charge of charcoal at 570° and the resulting gas was analyzed. The experiment was repeated with the addition of 20% of potassium carbonate to the charcoal. The first analysis showed that 19% of the carbon monoxide had been converted to carbon monoxide and carbon and, in the second case, the decomposition amounted to 29%. A catalytic effect is hereby demonstrated, and evidently the reasoning is orthodox.

**Heating Charcoal with the Catalyst.**—The idea that the catalysis of the reaction,  $C + CO_2 = 2 CO$ , was due to alternate reduction and re-formation of the alkali carbonates was suggested as a possible mechanism of the reaction. This might occur as follows.

This view was shown to be incorrect by heating some charcoal in an atmosphere of nitrogen, both alone and with 20% of potassium carbonate. The gases evolved during the heating were of the same composition (*ca.* 15% CO and 85% CO<sub>2</sub>) in each case, though a somewhat larger amount came off when the catalyst was present. Especially was it true that the gases came off more rapidly when the potassium carbonate was used than when the carbon was heated alone. The gases were presumably due to the decomposition of the surface complex of "fixed oxygen," or C<sub>x</sub>O<sub>y</sub>, described by Rhead and Wheeler,<sup>20</sup> and recently studied by Lowry and Hulett.<sup>11</sup> These facts seem to indicate that the surface compound may be more readily removed in the presence of substances such as potassium carbonate and that the cleaned surface is then more reactive toward carbon dioxide. If this be true, then the activity of the charcoal alone ought to be much greater after prolonged heating than at first, as a certain amount of the gases is removed finally, even in absence of potassium carbonate. This is correct to some extent, for the reaction of the charcoal with carbon dioxide is considerably greater after a period of heating when no gas is being passed than before, but very soon falls to exactly its original

<sup>20</sup> Rhead and Wheeler, *J. Chem. Soc.*, 103, 461 (1912).

activity after the passage of carbon dioxide has been resumed.<sup>21</sup> These results apparently indicate that carbon dioxide is able to reform the surface complex,  $C_xO_y$ , or that the gas is adsorbed in some intimate way and changes the reactivity of the carbon.

Rhead and Wheeler state<sup>20</sup> that the oxidation of carbon always consists in the formation of the indefinite oxygen-carbon complex and that this subsequently decomposes into carbon monoxide and carbon dioxide, since both these gases are shown to be primary products in the combustion of carbon. Hence it would appear that the oxidation of carbon by carbon dioxide must take place in some such manner. If carbon can take up carbon dioxide to form  $C_xO_y$ , and this complex then decompose to give carbon monoxide and carbon dioxide in a ratio dependent upon the temperature, and if such substances as potassium carbonate can catalyze these reactions, then we have a mechanism which explains the catalysis of the reaction,  $C + CO_2 = 2 CO$ , and consequently the catalysis of the reaction,  $C + 2 H_2O = CO_2 + 2 H_2$ .

**Adsorption of Carbon Dioxide.**—Whether or not a surface oxide is formed and decomposed in the manner indicated cannot be definitely stated. It is, however, certain that the presence in the carbon of such substances as potassium carbonate increases the concentration of carbon dioxide on the surface of the charcoal. This effect is more marked at temperatures higher than those at which adsorption ordinarily plays a part, and this is consistent with the fact that the specific catalytic effect of the same substances increases with temperature. We are inclined to regard such factors as strong presumptive evidence of a  $C-CO_2$  complex formation.

Table III gives a comparison of the catalytic effect of several substances

<sup>21</sup> Effect of heating the char. Eight g. of A909 was heated for 20 hours at 570°. The system was then washed out with  $CO_2$  for 10 minutes.

Passing  $CO_2$  at the rate of 14 cc./min., samples were collected successively.

	Time. Min.	CO produced. Cc.	CO per min. Cc.
(1)	21	13	0.62
(2)	20	8.5	0.425
(3)	35	7.5	0.21
(4)	60	9.5	0.16

Passage of  $CO_2$  was stopped, heating was continued at 570° for 17 hours.

Passing  $CO_2$  again at 14 cc./min. a sample was collected giving

(5)	2.5	20	8.0
-----	-----	----	-----

The system was washed out with  $CO_2$  for 15 minutes. Samples then collected.

(6)	15	5	0.33
(7)	30	6.5	0.22
(8)	40	7.0	0.17

After three hours with  $CO_2$  passing continuously at 14 cc./min., a sample was taken.

(9)	30	3.7	0.123
-----	----	-----	-------

This final value agrees with that given in Table II (0.124 cc./min.) obtained by the usual procedure of bringing the charge to 570° in about 2 hours, with  $CO_2$  passing through the system continuously.

upon the two reactions with their effect upon the adsorptive capacity of charcoal for carbon dioxide. The adsorption measurements were made by means of the apparatus described by Taylor and Burns.<sup>22</sup> The adsorption capacity of reduced nickel for carbon dioxide at 445° was there reported to be negligible. The adsorption on pure potassium carbonate at this temperature was also tested in the present experiments and was found to be practically nil.

TABLE III.

	Catalyst. %.	Interaction of C and H <sub>2</sub> O at 570°.	Interaction of C and CO <sub>2</sub> at 570°.	Adsorption of CO <sub>2</sub> per g. of C. at 445°.
		Gas produced. Cc./min.	Gas produced. Cc./min.	Cc.
20	K <sub>2</sub> CO <sub>3</sub> .....	25	2.3	4.4
20	Na <sub>2</sub> CO <sub>3</sub> .....	7.5	1.0	2.0
7.5	Ni.....	2.6 (final value)	7.7	1.76
20	NaCl.....	1.8	0.24	0.4
	No Catalyst.....	0.9	0.14	0.33

In the above table the only substance exhibiting anomalous behavior is reduced nickel. Its activity in the carbon dioxide-carbon reaction is above that of the other catalysts, but its effect upon the adsorptive capacity of carbon falls below that of the alkali carbonates. Its irregularity in the steam-carbon reaction was previously noted and discussed; the reason for its loss in activity in that case may also be applicable here.

There is a possibility, in favor of which however no evidence is as yet forthcoming, that steam might also be "fixed" on a carbon surface just as carbon dioxide is; that, moreover, catalytic agents such as potassium carbonate might in such case also bring about an increase in the concentration of steam on the charcoal surface. The experimental method of testing this possibility would not be simple since chemical reaction, to yield hydrogen and carbon monoxide, would occur in part. Furthermore, the technique of adsorption measurements with steam requires extended development before such a viewpoint can be satisfactorily taken.

#### IV. Summary.

1. The effect of certain catalytic agents upon the interaction of steam and carbon has been studied, using various forms of carbon.
2. It has been discovered that the interaction of carbon dioxide and carbon is likewise accelerated by the presence of the same materials, and a striking parallelism between the catalysts for the two reactions has been demonstrated.
3. The probable mechanism of the steam-carbon reaction has been investigated.
4. It has been shown that good catalysts for the water-gas reaction, for example, iron oxide, are ineffective in the steam-carbon and carbon dioxide-carbon reactions.

<sup>22</sup> Taylor and Burns, *THIS JOURNAL*, 43, 1273 (1921).

5. Catalysis of the water-gas reaction thus being excluded from consideration, it has been shown that the acceleration of the reaction  $C + CO_2 = 2 CO$ , and therefore the acceleration of the reaction,  $C + 2 H_2O = CO_2 + 2 H_2$ , may be ascribed to increased adsorption of carbon dioxide by the carbon surfaces in presence of active catalytic agents.

6. Adsorption measurements have been shown to confirm this view.

7. The results obtained have been considered in view of the proposed existence of a surface complex  $C_xO_y$ , and have been found to agree with this conception.

The authors of this paper wish hereby to thank Dr. R. M. Burns for his assistance in the adsorption measurements.

This research was carried out while Mr. Neville was the DuPont Fellow in Princeton; and it is desired to express to the DuPont Company an appreciation of their aid.

## THE ROLE OF MERCURY SALTS IN THE CATALYTIC TRANSFORMATION OF ACETYLENE INTO ACETALDEHYDE, AND A NEW COMMERCIAL PROCESS FOR THE MANUFACTURE OF PARALDEHYDE.

BY RICHARD R. VOGT AND JULIUS A. NIEUWLAND.

Received April 28, 1921.

It is well known that acetaldehyde can be prepared commercially from acetylene and water by the use of mercury salts as catalysts. A drawback to the process lies in the ease with which the mercury salt is reduced to the metallic state, and this rate of reduction depends upon the specific mercury salt used and the acidity and temperature of the solution in which it is dissolved. It seemed desirable to determine which type of mercury salt solution can best be used in this process and to investigate the mechanism of the reactions involved as the exact nature of the changes taking place is not as yet known. A study was accordingly made of the rate and duration of the reaction of acetylene using various mercury salts in solutions of the corresponding acids at different concentrations and temperatures. Mercuric sulfate in dil. sulfuric acid solution was found to be most suitable for this purpose on account of the cheapness, activity, and lasting qualities of this catalytic solution. It was found, however, that in these solutions the mercury did not long remain in the form of the sulfate but was converted to an organic compound, and this compound acted as the catalyst.

Some reduction of mercury compounds to metallic mercury took place

in the dil. sulfuric acid solutions, and there was also a tendency for the acetaldehyde to form undesirable condensation products. With higher concentrations of sulfuric acid there was a decrease in the reduction of the mercury catalyst but an increase in the quantity of acetaldehyde destroyed. In attempting to avoid this dilemma a process was devised in which acid sulfate solutions of high concentration were substituted for dil. sulfuric acid, resulting in the production of fairly pure paraldehyde with very little mercury reduction. Since paraldehyde can readily be converted into acetaldehyde and can also be substituted for it in many reactions, it is thought that this process may be of commercial value. A process was also devised for the utilization of the acetaldehyde for the formation of quinaldine directly in a rather conc. sulfuric acid solution of the catalyst. There was slight mercury reduction and little loss of acetaldehyde by formation of condensation products. This indicates the possible advantage of using the acetaldehyde directly in the catalytic solutions for further synthesis.

A dry catalyst was also employed, consisting of a mixture of an organic mercury compound with an acid sulfate of ammonia or one of the alkali metals, and moist acetylene or a mixture of acetylene and steam was thereby slowly converted into acetaldehyde with no reduction of the mercury compound and no destruction of the aldehyde. From this and other indications it appears that the reduction of mercury salts in these processes is in some way due to their hydrolysis in aqueous solutions.

### Experimental.

#### I. Investigation of the Use of Different Mercury Salts as Catalysts.

Instead of passing a continuous stream of acetylene through the catalytic solutions and allowing the excess of gas to escape as has commonly been done, in all of these experiments the solutions were placed in a closed absorption vessel from which all air had been displaced by acetylene and this vessel was connected through a wash bottle with a gasometer filled with acetylene. The gas was rapidly absorbed on shaking the catalytic solution, and the rate, amount, and duration of absorption could be accurately ascertained by noting the reading of the gasometer and the flow of gas through the wash bottle, and by taring the absorption vessel.

It was soon found that many mercury salts in both acid and neutral solutions when shaken with acetylene would absorb it rapidly for a short time with the formation of precipitates, but that none of the neutral solutions and only a few of the acid solutions would continue to absorb readily after the precipitation had ceased.

Thus on the one hand, mercuric chloride in dil. hydrochloric acid and mercuric bromide in dil. hydrobromic acid absorb acetylene slowly for a time and then cease entirely to do so; while in stronger acid solution or in

concentrated solutions of halide salts no reaction occurs. Mercuric acetate in acetic acid solution also failed to react with acetylene after precipitation was complete, and mercuric phosphate in phosphoric acid solutions only absorbed acetylene very slowly after the initial reaction was over. *It is characteristic that the acetylene compounds of all of these salts were found to be only slightly soluble in the corresponding acids.*

On the other hand, mercuric perchlorate in perchloric acid, mercuric fluoborate in fluoboric acid, and mercuric nitrate in nitric acid, several of the mercuric sulfonates of the aromatic series in the sulfonic acids, and mercuric sulfate in sulfuric acid continued to absorb acetylene for a long time. *The acetylene compounds of all of these salts were found to be markedly soluble in the corresponding acids.* No acetaldehyde could be obtained from the nitric acid solutions, and the perchlorate, fluoborate, and sulfonates were considered too expensive for commercial use.

In view of these results the action of mercuric sulfate was submitted to a closer examination. It was found that in sulfuric acid of less than 20% concentration the catalyst is always reduced to metallic mercury with objectionable rapidity, on reaction with acetylene. The ratio of acetaldehyde formed to mercury salt reduced is accordingly very narrow in such a solution. With a sulfuric acid in concentrations above 20% the acetaldehyde cannot be distilled at ordinary pressure without the formation of large quantities of crotonaldehyde and tarry by-products, and the methods that have been devised for separating the acetaldehyde with organic solvents or of volatilizing it with excess acetylene or under reduced pressure are complex and expensive. We have accordingly studied the cause of these difficulties and have originated new processes in which they are at least partially obviated.

## II. The Nature of the Catalyst Compounds and the Cause of their Reduction to Metallic Mercury.

Exact information concerning the nature of the catalyst mercury compounds is very difficult to obtain by analytical methods on account of the high molecular weight of mercury, the inaccuracy of mercury determination, the constantly changing state of the catalyst, and the probability of the presence of numerous impurities in it. It has been frequently supposed that the inorganic salts of mercury acted as carriers of acetylene, but if this were the case some of the inorganic salt would be continually regenerated, especially if the supply of acetylene were shut off. However, no yellow mercuric oxide can ever be isolated from these mixtures by the addition of alkaline hydroxides; only white or gray organic substances are obtained in this way. It was not possible to detect any inorganic salts of mercury in any of the catalytic mixtures after the absorption of acetylene. The catalyst prepared from mercuric sulfate, moreover, always contained the

sulfate radical and at least one attached acetylene residue. The empirical formula,  $3\text{HgO} \cdot 2\text{C}_2\text{H}_2$ , has been fairly well established for the precipitate obtained by treating mercuric acetate in dil. acetic acid with acetylene.<sup>1</sup> When this compound is dissolved in dil. sulfuric acid it behaves in every way exactly like the compound precipitated from mercuric sulfate solutions with acetylene. It is therefore assumed that the precipitate from mercuric sulfate solutions is the sulfate of the same radical of which the precipitate from mercuric acetate is the oxide; and what appears to be a possible structural formula for this catalytic compound is given below. It is slightly soluble in strong alkaline solutions, and can be precipitated from such solutions with additional acetylene. Sulfuric acid releases a small quantity of acetaldehyde from this precipitate thus showing in two distinct stages the probable action in acid solutions. Small crystals of this catalyst can be obtained by dissolving it in warm dil. sulfuric acid and then cooling the solution.

The following reactions illustrate this point of view.

As far as is known, some acid is always liberated by the action of acetylene on the salts of mercury. It will be noted in the above reaction that the mercuric sulfate appears to supply all of the acid that is necessary, but nevertheless acid is always added to catalytic solutions in actual practice. An attempt was made to form acetaldehyde by passing moist acetylene over various mercury salts in the solid state. Mercuric chloride did not react with acetylene under these conditions. Nitrous fumes were liberated from mercuric nitrate by this method, but no acetaldehyde could be detected. From the reaction of mercuric sulfate with moist acetylene, acetaldehyde and free sulfuric acid resulted, and the acid immediately charred and polymerized a part of the aldehyde. When, however, moist

<sup>1</sup> Plimpton, *Chem. News*, 65, 295 (1892).

acetylene at  $100^{\circ}$  was passed over a dry finely divided mixture of sodium sulfate and mercuric sulfate, the sulfuric acid which was liberated combined with the sodium sulfate to produce sodium hydrogen sulfate, there was no charring, and a considerable quantity of pure acetaldehyde was produced. It was thus demonstrated that, under these conditions, mercuric sulfate will furnish all of the acid necessary for carrying on the reaction according to theory.

As a side reaction in all of these catalytic processes we are likely to have the continual reduction of mercury compounds to the metallic state, and this is a very serious commercial disadvantage. Numerous attempts have been made to prevent the reduction of mercury salts by the use of oxidizing agents in the solution. It is understood that none of these has proved of any value in practice. The salts of iron, manganese and vanadium were tried without securing any favorable results.

In general it was found that the greater the dilution of an acid solution the more rapidly mercury salts were reduced in it by the action of acetylene; and it is to be noted that the dilution of the acid is also closely related to the hydrolysis of mercury salts. The solutions of those mercury salts which hydrolyze most readily in their corresponding acids are also those in which the most rapid reduction takes place. Thus in dil. hydrochloric acid there is little reduction; in dil. sulfuric, somewhat more; in dil. nitric or acetic, a great deal. This leads us to the conclusion that, perhaps, most of the reduction of mercury salts is due to the action of acetylene or acetaldehyde on hydrolyzed mercury compounds, containing an oxide or hydroxyl group instead of an acid radical. Moist mercuric oxide is reduced by acetylene more rapidly than any other mercury compound. We find that this theory is also supported by the fact that in alcoholic solutions both hydrolysis and reduction are less than in aqueous solutions. It should be remembered that the catalytic mercury compounds, being organic, will probably hydrolyze much more in concentrated acid solutions than the corresponding inorganic salts.

On the other hand, we find some mercuric catalytic compounds reduced in conc. sulfuric acid where there is little possibility of hydrolysis. Charring of the organic matter always takes place in such solutions with the formation of sulfur dioxide. This substance will reduce mercury salts even in strong acid solutions, and the reduction in conc. sulfuric acid is thus accounted for.

The only way in which acetaldehyde could be obtained without the reduction of any mercury salt whatever was by the action of a stream of moist acetylene at  $70^{\circ}$  to  $120^{\circ}$  on a dry mixture of the mercuric sulfate acetylene compound and sodium, potassium, or ammonium hydrogen sulfates. This mixture could be made either by the action of moist acetylene on mercuric sulfate and the normal sulfates of sodium, potassium

or ammonium finely ground together, as explained above; or the acid salt could be added to the washed and dried precipitate obtained from an acid mercuric sulfate solution by the action of acetylene. From such a mixture only about one gram of acetaldehyde per gram of mercury could be obtained in 12 hours, but there was no reduction of the mercury compound and the mass was perfectly soluble in water after use. When an excess of moisture or steam was used with the acetylene, a little of the mercury compound was volatilized. While this method may not be of much practical value, it serves to confirm the belief that the reduction of mercury compounds by acetylene is in some way due to their hydrolysis in dilute acid solution and points to the advantage of using stronger acid whenever possible.

It can also be shown that metallic mercury is slowly dissolved by the more concentrated solutions of sulfuric acid and the acid sulfates, but with acid strengths below 15% which have frequently been used for this purpose, this action is almost negligible.

The advantages of stronger acidity of the catalytic solutions having thus been demonstrated it became necessary to devise either a method for separating aldehyde from such strong acid solutions without the formation of undesirable by-products, or a method of utilizing the aldehyde directly in the solution for further synthesis and in this way avoiding the difficulties of separation.

### III. The Preparation of Quinaldine.

The acetaldehyde in these catalytic solutions was successfully substituted for pure acetaldehyde in the preparation of quinaldine. According to a standard process quinaldine is manufactured by treating aniline in hydrochloric acid or sometimes in sulfuric acid solution with a large excess of acetaldehyde or paraldehyde.

In the following process cheap acetylene takes the place of acetaldehyde. More concentrated sulfuric acid than can be used in making acetaldehyde from acetylene can be employed without the formation of tarry by-products. The violence of the standard quinaldine reaction is also avoided, giving more suitable conditions for manufacture on a large scale. In the old method a considerable excess of acetaldehyde was necessary, and in the new also it was found best to use an excess of acetylene. This can readily be done, since a given volume of the catalytic solution will absorb so much acetylene that the addition of a proportionate amount of aniline makes the mixture too viscous to handle.

Since quantities of a substance corresponding in properties to the

trimethyl-quinoline below indicated have been obtained in the process to be described, it is probable that under the conditions the following reaction takes place to a considerable extent in addition to the one which occurs in the regular process.

The following example will make clear the procedure.

Two g. of mercuric sulfate and 400 g. of aniline sulfate were dissolved in one liter of 40% sulfuric acid at 60° in a 2-liter flask which was then filled with acetylene, stoppered, and connected by a tube to a supply of acetylene under slight pressure. At this temperature fairly rapid absorption of the gas began at once but the speed was greatly accelerated by shaking the flask at frequent intervals. In a later experiment the same result was attained by using a drip absorption tower. In about 6 hours when 200 g. of acetylene had been absorbed, sodium carbonate was added until the solution was only slightly acid to litmus. The solution was then filtered and the precipitate contained practically all of the by-products, among them the substance thought to be trimethyl-quinoline above referred to. The filtrate was then made strongly alkaline with sodium hydroxide, causing the quinaldine and a small excess of aniline to separate as an oil. The quinaldine was purified by the ordinary methods and gave a yield of 80 g., which compares well with ordinary yields from the present commercial process.

Fifty g. of the dried by-product precipitate was heated for 5 hours at 200° with 50 g. of phthalic anhydride and 50 g. of zinc chloride, and the mass was then dissolved in hot conc. sulfuric acid and diluted in a process similar to the process for making quinophthalone from quinaldine. Considerable quantities of an orange dye were obtained showing that the original by-products were probably substituted quinaldines. The dye has properties very similar to quinophthalone, but produces an orange instead of a yellow color. The yield from the crude precipitate was only half of that calculated for trimethyl-quinoline of the same weight, on the basis that the phthalone was formed in the usual manner.

The concentration of the sulfuric acid used in these experiments varied from 10% to 95%. The temperature varied from 20° to 100°. A concentration of about 40% of sulfuric acid and a temperature of 60° seemed most advantageous. The use of phenol sulfonic and toluene sulfonic acids gave the same results as sulfuric acid. Aniline dissolved in 35% perchloric acid containing mercuric perchlorate gave very little quinaldine with acetylene and a large amount of the supposed trimethyl-quinoline. This substance separated from the acid solution and could be removed without neutralization.

The precipitate formed by the acetylene from mercuric acetate solutions was frequently used as a catalyst instead of the mercuric sulfate compound, and gave very satisfactory results.

It was found that the addition of acetone to the solution hastened the reaction, probably by increasing the solubility of the acetylene.

The aniline sulfate may be added at the beginning of the process, or while the absorption is going on, or aniline may be added when the absorption is complete, thus

neutralizing part of the sulfuric acid. It was found best to add at least part of the aniline as sulfate at the start as this tended to prevent the polymerization of acetaldehyde to tarry by-products.

It has been found possible to recover a portion of the excess acetaldehyde formed from the excess acetylene by diluting the sulfuric acid to a concentration of less than 10% and distilling the aldehyde.

The action of substituted anilines is exactly analogous; the toluidines, for example, yield the corresponding methyl-quinolines.

It will be noted that according to theory no water is used in this reaction, and this led to an attempt to carry on the process by using aniline sulfate, sodium hydrogen sulfate, mercuric sulfate, and acetylene in a nearly dry state. Acetylene was absorbed rapidly at first and some quinaldine was formed, but the mass soon became a viscous semi-solid into which the acetylene could not penetrate.

It was also found that the preparation of quinaldine could be carried on in absolute alcohol solution with dry acetylene. This points to the possibility that acetaldehyde may not be an intermediate product, but that the aniline may react directly with the mercury acetylene compound.

The preparation of aldehyde green is a related reaction that can also be performed with acetylene instead of acetaldehyde or paraldehyde. A present standard method for the synthesis of the commercial product is to treat fuchsin in rather strong sulfuric acid with about  $\frac{1}{3}$  of its weight of paraldehyde, then boil with sodium thiosulfate, filter, and treat the filtrate with sodium acetate. In this experiment 40 g. of fuchsin was dissolved in 100 g. of 50% sulfuric acid, containing 1 g. of mercuric sulfate, and the solution was allowed to absorb 7 g. of acetylene. It was then boiled with 5 g. of sodium thiosulfate, filtered, and treated with 8 g. of sodium acetate. Both a green and a blue dye were present. The mixture did not absorb acetylene very readily, but this may have been due to the presence of chloride in the fuchsin.

#### IV. Preparation of Paraldehyde.

It was often noted that when solutions containing acetaldehyde were allowed to stand for a few days an odor of paraldehyde developed, and in a few cases droplets of paraldehyde separated from perchloric and sulfuric acid solutions. It was next found that a mixture of sodium hydrogen sulfate and mercuric sulfate in a moist state became covered with a film of paraldehyde when acted upon by acetylene and this action is the basis of the process to be discussed.

The most convenient apparatus for carrying on this reaction in the laboratory is a large bottle or carboy filled with fragments of glass or porcelain. These are covered with a pasty mass made up of an acid salt, a catalytic mercury compound, and a small amount of saturated aqueous solution of the acid salt. The air in the apparatus is then displaced by acetylene, the carboy tightly stoppered, and acetylene led into the apparatus as fast as it is used. The carboy is rolled occasionally to keep the catalytic mixture evenly distributed

Mercuric sulfate, mercuric acetate, the acetylene compounds of the two salts precipitated from acid solution, and mercuric oxide were used in different experiments without markedly different results. Mercuric phosphate was not so good.

Acid phosphates and sulfates of ammonium, sodium, and potassium were experimented with. The acid phosphates were discarded because of their slow action and high mercury reduction. Sodium hydrogen sulfate is the cheapest material and is perfectly satisfactory for this purpose. Ammonium hydrogen sulfate solutions dissolved more acetylene and more of the resulting paraldehyde than any of the others.

The solution of acid salt must be saturated because reduction of mercury takes place more readily in dilute solutions, and it is best to have an excess of undissolved acid salt in the apparatus in order to saturate rapidly any water that may be added from time to time. As little solution as possible was used in most of these experiments, because larger amounts dissolved the paraldehyde and retarded its separation. Since the saturated solutions of the acid sulfates do not dissolve either acetylene or the mercury acetylene catalytic compound to a very great extent, it is necessary to have the acetylene come in direct contact with the solid catalyst, and this is prevented by the presence of much solution.

In this process acetaldehyde is first formed by the action of the mercury acetylene compounds on acetylene and water. The acid salts at ordinary temperatures and in saturated water solutions or in solid form, then rapidly and completely polymerize the acetaldehyde to paraldehyde. As paraldehyde is but slightly soluble in saturated solutions of the acid salts, it separates as a distinct layer and may be drained off in a fairly pure condition. The paraldehyde shows little tendency to cling to the catalyst mixture as long as this is protected by a film of moisture, and no solid matter is ever suspended in the paraldehyde.

The absorption of acetylene is more rapid after a certain amount of paraldehyde has been formed in the apparatus. The reason is that the paraldehyde dissolves the unconverted acetaldehyde vapor which would dilute the acetylene and thus slow up absorption and also because paraldehyde dissolves acetylene and brings it into more immediate contact with the catalysts.

The water needed in the reaction can be partially supplied by using moist acetylene, but more water must be added as often as the amount in the apparatus diminishes. It is better to add the water in small amounts and with thorough mixing, as a sudden dilution causes a sudden and notable graying and reduction of the mercury.

Considerable amount of certain impurities, especially the halides retard the absorption of acetylene greatly. Free sulfuric acid hastens absorption but the resulting paraldehyde is dark in color and contains

traces of crotonaldehyde. It should be noted that when mercuric sulfate reacts with acetylene sulfuric acid is liberated, and this will produce the same effect in a mixture as added sulfuric acid. When mercury is introduced in the form of sulfate it is best to add a small amount of the normal salt corresponding to the acid salt used to take up any free sulfuric acid that may be formed in this way. When this precaution is observed the paraldehyde is clear and colorless, and the excess of normal salt does not materially affect absorption.

The following example of laboratory procedure will serve to illustrate the process.

A 2-liter bottle was filled with clean dry glass fragments, and a mixture of 10 g. of mercuric sulfate, 40 g. of sodium hydrogen sulfate and 20 g. of water was then distributed over the surface of this packing material. The air was displaced by acetylene and the bottle tightly closed except for the inlet tube through which moist acetylene under slight pressure was continuously supplied from a gasometer. As soon as the white compound of acetylene and mercuric sulfate had been formed, acetaldehyde could be detected in the apparatus, and shortly afterward paraldehyde was also shown to be present. When about 25 g. of acetylene had been absorbed, paraldehyde began to accumulate in visible drops. Thereafter the formation of paraldehyde was practically quantitative. The production from the apparatus used was about 60 g. per day, and the total amount obtained was 287 g.

In another experiment a mixture of 295 g. of sodium hydrogen sulfate, 250 g. of water, and 75 g. of mercuric nitrate was used in the same way. Ten cc. of nitric acid was added at the end of both the fifth and ninth day, and this seemed to redissolve some of the reduced mercury and increase absorption slightly. Water was added in small quantities as needed. The paraldehyde was drained off daily, and at the end of the tenth day when the experiment was accidentally lost, the total amount obtained was 1100 g.

A mixture of 1250 g. of ammonium hydrogen sulfate, 200 g. of water, and 300 g. of mercuric nitrate was allowed to absorb acetylene for a few days before the separation of paraldehyde began. It then yielded from 300 to 500 g. of paraldehyde per day, with some interruptions due to lack of acetylene, and at the time of this writing is still running and has given a total yield of 3400 g. of paraldehyde, an aldehyde-mercury ratio of 17:1.

A mixture containing 200 g. of potassium hydrogen sulfate, and 50 g. of mercuric sulfate with frequent small additions of water absorbed acetylene for 130 days. Twenty-five g. of mercuric sulfate was then added and the experiment was carried on for 35 days longer. A total yield of 1800 g. of paraldehyde was obtained, giving an aldehyde-mercury ratio of 35:1.

The paraldehyde prepared by this method contains a small amount of dissolved water and acid salt, and, if the separation takes place immediately after absorption, unchanged acetylene and acetaldehyde may be present. These impurities were never found to run higher than 5%. The heat of formation of the paraldehyde did not appear to be as great as was expected. A 20-liter carboy of the mixture distributed over glass fragments absorbed acetylene at the rate of 2 liters per minute.

### Summary.

It was shown by experiments on the relative value of different mercury salts as catalysts for the conversion of acetylene to acetaldehyde that

mercuric sulfate in sulfuric acid solution is the cheapest and most efficient for the purpose. It was found that the chief difficulties in its use lie in the impossibility of separating acetaldehyde from the more concentrated acid solution and in the rapid reduction of the mercury compounds in the dilute acid which is now commercially employed. The reduction of mercury compounds by acetylene and aldehyde is greatest where the conditions are the most favorable for hydrolysis, and the catalytic mercury compounds being organic are probably more readily hydrolyzed than the inorganic salts of mercury. No reduction takes place in a suitable dry mixture where there is no hydrolysis but this method is too slow for commercial use. Attention was therefore turned to methods of utilizing acetaldehyde in rather concentrated solutions of sulfuric acid or the acid sulfates.

A new method for the synthesis of quinaldine and related products has been worked out. A new paraldehyde process has been developed which is capable of being used as a substitute for the method of acetaldehyde production now in use and which has the following advantages: (1) the ratio of aldehyde to reduced mercury is much higher; (2) the apparatus is simpler and the catalyst less bulky; (3) no distillation or separation process is necessary; (4) there are no by-products and no waste products; (5) there is no excess acetylene to be recovered.

## THE EXISTENCE AND REACTIONS OF POSITIVE HALOGEN ATTACHED TO CARBON IN AROMATIC COMPOUNDS.

BY BEN H. NICOLET.

Received May 4, 1921.

The halogen atoms in certain organic compounds have the property of being replaced by hydrogen, and appearing combined with the hydroxyl group as hypohalous acids, on hydrolysis. This behavior is frequently expressed by referring to such atoms as positive halogen atoms. Most, if not all, of the compounds in which halogen replaces the hydrogen of an hydroxyl, amino, or imino group, have this halogen in the positive form.

Without doubt, halogen attached to carbon is usually negative. Nevertheless, Howell and Noyes<sup>1</sup> have recently offered excellent evidence that iodine is positive in the compound  $C_2I_2$ . Fry<sup>2</sup> had previously assigned a structure involving positive chlorine and bromine, to certain aromatic compounds, but primarily on the ground of the extreme difficulty of hydrolyzing such compounds. The negative test of non-reaction is necessarily an uncertain basis for the assignment of electronic structures.

<sup>1</sup> Howell and Noyes, *THIS JOURNAL*, **42**, 991 (1920).

<sup>2</sup> Fry, *ibid.*, **38**, 1327, 1333 (1916).

It is the object of the present paper to call attention to certain aromatic halogen compounds whose reactions are such as would be expected if the halogens were in the positive form. Typical of all these cases so far examined, is the reaction observed by Wheeler and Liddle,<sup>3</sup> which takes place when 3-iodo-4-aminobenzoic acid is boiled for a "few minutes" with hydrochloric acid.

Obviously, iodine is here removed in such a manner as to be replaced by hydrogen; and yet the first stage of the reaction can scarcely involve a reduction, since the iodine thus removed is capable of resubstitution in the benzene ring. The latter reaction is only given by positive iodine. The formation of the di-iodo derivative is thus fairly good evidence of the intermediate formation of some product such as represented by the formulas HOI or CII, and confirms the positive nature of the original halogen.

Similar reactions have been observed by Limpricht<sup>4</sup> on several amino-bromo-benzene sulfonic acids, and by Fittig<sup>5</sup> on *p*-bromo-aniline. In both cases, however, temperatures of 150° or higher were necessary.

It has now been found that 3-iodo-4-aminotoluene, 4-iodo-aniline, 3-bromo-4-acetamino-toluene, and 3-iodo-4-hydroxybenzoic acid, when boiled with 10% hydrochloric acid, are hydrolyzed with a readiness decreasing in the order named, in such a way that the halogen is removed and replaced by hydrogen; and further that the halogen is in each case re-substituted in the benzene ring to give di-(or tri-) halogen substitution products. This is considered to be the best evidence yet offered for the existence of "positive" halogen attached to carbon in the benzene nucleus. It will be noticed that in all the cases mentioned the halogen in question is *ortho* or *para* to a strongly negative group.

It has also been found that alkali is incomparably less effective than acid in removing such "positive" halogens, as was to be anticipated. This is true even when sodium arsenite is added to the alkaline solution; but this is not particularly surprising, since in acid solution also, the product of hydrolysis, HOX, is effectively removed, either by resubstitution or by conversion to HX and HXO<sub>3</sub>.

In the presence of stannous chloride, naturally, the same hydrolysis takes place; but here resubstitution is prevented, and the halogen is simply removed from the molecule. This reaction, involving as it does the

<sup>3</sup> Wheeler and Liddle, *Am. Chem. J.*, **42**, 453-7 (1909).

<sup>5</sup> Fittig, *Ann.*, **188**, 20, 24, 28 (1877).

use of a reducing agent, is valueless for the proof of electronic structure, but in the few cases investigated it runs so definitely parallel to the action of acid alone, that it may yet prove valuable as a preliminary test for positive halogens in aromatic compounds.

The present paper is purely preliminary, and further work is contemplated on all the questions raised, particularly as regards aromatic derivatives.

### Experimental Part.

**3-Iodo-4-aminotoluene.**—The base was prepared according to Wheeler and Liddle.\* Boiled with 10% hydrochloric acid, the color of iodine vapor was visible almost at once and at the end of 10 minutes, di-iodo-toluidine could be isolated. An hour's boiling was sufficient (perhaps more than sufficient) to give complete conversion to toluidine and 3,5-di-iodo-toluidine, both of which were identified.

**3-Bromo-4-acetamino-toluene.**—On boiling for an hour with 10% hydrochloric acid, noticeable amounts of 3,5-dibromo-toluidine had sublimed into the condenser. The reaction is however much slower than that of the iodine compound, as even after boiling for 5 hours, only 6-7% of the theoretical amount of the dibromo-derivative had been formed, and on re-acetylation, most of the original material was recovered unaltered. Toluidine was identified only by the color reaction with sodium hypochlorite.

**4-Iodo-aniline.**—Boiling with 10% hydrochloric acid seemed to cause liberation of iodine readily (as judged by the color), but after an hour the transformation was far from complete. The solution contained aniline, and a mixture of iodoanilines.

**3-Iodo-4-hydroxybenzoic Acid.**—After an hour's boiling, an appreciable amount of the di-iodo acid had separated from the originally clear solution. At the end of 6 hours, the yield of 3,5-di-iodo-4-hydroxybenzoic acid was only 6.7% of that theoretically possible, and much unaltered product was isolated.

**Action of Alkalies.**—Mono-iodo-toluidine was recovered quantitatively unaltered after heating for 3 hours with an excess of alkaline sodium arsenite solution in dil. alcohol. The solution gave no test for iodide. Refluxing for 3 hours with 10% alcoholic potash was also without effect, and did not produce an odor of isocyanide. (Alcohol reacts much more readily than do aromatic amines, with alkaline hypo-iodites; when iodine is added to an alkaline alcoholic solution of aniline, for instance, the isocyanide odor appears promptly and unmistakably.)

**Action of Mild Reducing Agents in Acid Solution;  $\text{SnCl}_2$ .**—The various substances were boiled under reflux with 10% hydrochloric acid containing an excess (2 mols.) of stannous chloride.

**4-Bromo-aniline**, after one hour, scarcely gave a color test for aniline. After 5 hours the test was very distinct; but at the end of 8 hours most of the original bromo-aniline was recovered unchanged.

**3-Iodo-4-aminotoluene**, heated for one hour, gave practically pure *p*-toluidine, m. p.  $42^\circ$ , which liquified on mixing with the original base.

**3,5-Di-iodo-4-aminotoluene**, after 8 hours, had gone into solution almost completely. Steam distillation of the alkaline solution gave *p*-toluidine, recognized by its color reaction with hypochlorite, and by its acetyl derivative, m. p.  $152^\circ$ .

**4-Iodo-aniline**, heated for one hour, gave tests for aniline and for iodide. After 4 hours, the reaction was somewhere near complete, as steam distillation gave a liquid base, whose crude acetyl derivative, melted at  $113^\circ$ .

**3-Bromo-4-acetamino-toluene** gave qualitative indications of reaction after one hour. After 8 hours, debromination was slightly more than 75% complete.

3-Iodo-4-hydroxybenzoic acid, after one hour, showed little sign of reaction. After 5 hours, the solution contained considerable iodide, but the reaction was very incomplete.

Iodobenzene, treated as above and boiled for 5 hours, showed no evidence whatever of reaction. The same result was obtained when alcohol was added to render the substance more soluble. In both cases the test for iodides was negative.

### Summary.

1. It has been shown that certain compounds containing iodine or bromine *ortho* or *para* to an amino or anhydroxyl group, when boiled with hydrochloric acid in part replace their halogen by hydrogen and in part give di- (or tri-) substitution products. Together, these reactions are considered to characterize these derivatives as containing positive halogen.

2. In similar compounds, iodine is more positive than bromine, and *ortho* than *para* compounds.

3. Compounds which, by the above standards, contain positive halogen, are abnormally readily dehalogenated by stannous chloride, in acid solution.

## NITROMALIC ACID.

By ARTHUR LACHMAN.

Received May 12, 1921.

The abnormal action of alkalis upon organic nitrates, whereby varying and at times considerable amounts of nitrous acid are produced, has been accounted for in two quite different manners. Nef<sup>1</sup> assumed what he called "methylene dissociation" to take place, and definitely ascribed this dissociation to the alkali. Klason and Carlson,<sup>2</sup> holding the view that nitric acid is a peroxide, looked upon the formation of nitrous acid as a direct hydrolysis of the nitric ester into nitrous acid and an organic peroxide. They also regarded the alkaline reagent as an essential factor.

The recently noted behavior of nitrotartaric acid,<sup>3</sup> hydrolyzing normally and almost quantitatively as a true nitric ester in strongly acid media, and equally quantitatively as a nitrous ester in weaker acid, did not accord with either of the above interpretations. The suggestion was made that nitrotartaric acid goes over into a pseudo form,  $\text{COOH.CH(ONO}_2\text{).CH(ONO}_2\text{).COOH} \rightarrow \text{COOH.C(OH)(ONO).C(OH)(ONO).COOH}$ . Nitrotartaric acid, being soluble both in water and organic solvents, seemed to offer a better opportunity for the investigation of what really happens in these intramolecular oxidations, than the esters studied by Nef and by Klason and Carlson. At the same time, Michael's view that

<sup>1</sup> Nef, *Ann.*, 309, 176 (1899).

<sup>2</sup> Klason and Carlson, *Ber.*, 40, 4183 (1907).

<sup>3</sup> Lachman, *THIS JOURNAL*, 43, 577 (1921).

the *solvent* frequently determines the course of a reaction, could be considered.

It proved difficult, however, to keep nitrotartaric acid under sufficient control for purposes of measurement. The search for a more suitable compound was fortunately of brief duration. Nitromalic acid, the nitrate of ordinary malic acid, soon gave promising results. This acid, which has not yet been described, is easily prepared.

### Preparation and Properties of Nitromalic Acid.

Dissolve 10 g. of malic acid in 20 cc. of nitric acid (1.42), warming slightly if necessary. Add this solution, with careful cooling and stirring, to 40 cc. of fuming sulfuric acid (10–15%). Pack this material in ice, and allow it to stand for 2 hours. Pour the product upon cracked ice, extract the liquid twice with ether, wash the ether and extract it thrice with small quantities of ice water to remove the excess of nitric acid. Dry this solution thoroughly with calcium chloride. Careful evaporation of the ether gives a thick white oil, which soon solidifies to form a stellated mass of long, soft, white needles. Yield, 6 to 7 g.<sup>4</sup>

Nitromalic acid as thus obtained is sufficiently pure for analysis; a portion, however, was recrystallized from dry ether by addition of ligroin. It melts, with decomposition, at 110–112°. It is very soluble in water, alcohol, ether, and acetone, and is insoluble in ligroin and benzene. The composition is  $C_4H_5NO_7$  corresponding to the structure  $COOH.CH_2-CH(ONO_2).COOH$ ; mol. wt., 179.1.

Subs., 1.0054: 22.45 cc. of 0.5 N NaOH.<sup>5</sup> Calc.: 22.47 cc.

Subs., 0.5044: (boiled with excess of diluted 0.5 N NaOH, cooled and titrated) 17.15 cc. Calc.: 17.05 cc. for 1.5 moles.

The *sodium* salt of nitromalic acid was prepared by carefully neutralizing the acid with sodium carbonate, and evaporating the solution at room temperature over sulfuric acid. It forms small hard white crystals, is very soluble, but not deliquescent. It holds two molecules of water. The dry sodium salt explodes when heated.

*Analysis.* Subs., 0.0897:  $Na_2SO_4$ , 0.0500. Calc. for  $Na_2C_4H_5NO_7 \cdot 2H_2O$ : Na, 17.75. Found: 18.25.

The *silver* salt was prepared by addition of silver nitrate to a solution of the sodium salt. It forms small white crystals, and is moderately soluble in water. It is anhydrous. On heating, it explodes. For analysis, it was moistened with ammonium sulfide, and then ignited.

*Analysis.* Subs., 0.2321: Ag, 0.1271. Calc. for  $Ag_2C_4H_5NO_7$ : Ag, 54.9. Found: 54.8.

<sup>4</sup> It is not desirable to prepare nitromalic acid in larger amounts. A lot made from 30 g. of malic acid, from which the ether was evaporating spontaneously, exploded during the night. A second preparation with similar quantities decomposed during the evaporation of the ether.

<sup>5</sup> Nitromalic acid is not strong enough to be titrated with methyl orange as an indicator. The above titrations were made at 0°, with phenolphthalein as an indicator. Combustion gave high results for C, because of formation of nitric oxide. Calc.: H, 2.79. Found: 2.85.

### Hydrolysis by Aqueous Alkali.

Nitromalic acid was treated with sodium hydroxide in water solution; both concentration of the acid and the excess of the alkali were varied within wide limits. The reaction was completed very rapidly; 5 minutes' heating on the water-bath sufficed. Temperature seems to have no effect on the production of nitrous acid; in two cases, the reaction mixture was allowed to stand in the cold for several days. The results obtained are given in the following table.

TABLE I.

#### HYDROLYSIS BY AQUEOUS ALKALI.

Nitromalic Acid, Weight. G.	Millimols.	NaOH, Millimols.	Volume. Cc.	NaNO <sub>2</sub> . %.
0.3056	1.7	10	70	21.0
0.5170	2.9	18	9	21.6
0.5009	2.8	55	9	21.0
0.1790	1.0	12	30	20.3
0.2720	1.5	30	10	20.6

The amount of nitrous acid formed is practically constant, regardless of temperature, concentration, or excess of alkali. This is in complete agreement with the data obtained by Klason and Carlson<sup>2</sup> who studied the hydrolysis of alkyl nitrates by alkalies in the presence of mercaptans.

The method of estimating the amount of nitrous acid produced in the above hydrolyses must be described briefly, as it subsequently led to interesting results. The small flasks containing the reaction mixture were connected to a carbon dioxide supply and when all the air had been swept out, to an azotometer. A solution of a slight excess of sulfanilic acid in dil. acetic acid was then added all at once through a dropping funnel. After allowing the diazo reaction about 5 minutes in which to complete itself, the material in the flask was slowly warmed to boiling; nitrogen is evolved so rapidly that the entire operation required about 20 minutes. Each mol. of nitrous acid gives one mol. of nitrogen.

### Hydrolysis by Alkali in Methyl Alcohol.

Upon the addition of sodium hydroxide, dissolved in methyl alcohol, to a solution of nitromalic acid in the same solvent, a portion of the sodium nitromalate first formed by neutralization, is precipitated. In spite of the lack of homogeneity in the system, the amount of nitrous acid formed is again practically independent of temperature, concentration, or excess of alkali; *but nearly twice as much is produced as when water is the solvent.*

TABLE II.  
HYDROLYSIS BY ALKALI IN METHYL ALCOHOL.

Weights G.	Nitromalic Acid. Millimols.	NaOH. Millimols.	Volume. Cc.	NaNO <sub>2</sub> . %.
0.5353	3.0	9.2	5	32.6

0.5163	2.9	50	20	34.4
0.3775	2.1	17	15	35.5
0.3163	1.8	10	23	34.6
0.2383	1.3	30	30	35.6

### Hydrolysis in Acid Solution.

The preceding data pointed to the conclusion that the solvent is the determining factor in the abnormal hydrolysis of nitrates; but on further consideration it became clear that what was measured above was not the formation of nitrous acid, *but the competition between two or three different reactions.*

Reaction I represents the normal hydrolysis of nitromalic acid into its components. Reaction II is the process of isomerization according to the present conception; it might represent equally well, with a slight change in formulation, what Nef called "methylene dissociation," or Klason's "peroxide formation." Reaction III is the simple hydrolysis of the nitrous ester.

Klason and Carlson have found that the normal saponification of a nitrate takes a measurable time, while the hydrolysis of nitrites is practically instantaneous. The data obtained above, then, represent the ratios of the velocities of Reactions I and II; and any influence that can be exerted upon Reaction I to slow it down, will inevitably increase the proportion in which Reaction II takes place.

This makes clear the influence of methyl alcohol upon the amount of nitrous acid produced; Reaction I requires water for its mechanism, and as the amount of water present is very small, it must be greatly retarded. Consequently, more time is available for the structural change, and more nitrous acid is found.

It is further clear that if Reaction I could be retarded still further, even more nitrous acid might be expected. With this purpose in mind, alkali was excluded altogether, and nitromalic acid warmed directly with aqueous sulfanilic acid.

Nitrogen was found to be given off slowly, and at a rapidly diminishing rate. The first experiment was maintained for 2 hours at water-bath

temperature, and gave 65% nitrogen. A second test, lasting 5 hours, gave 78.3%.

These striking figures at once eliminate the hypotheses of Nef and of Klason.

### Velocity of the Structural Change.

The very moderate rate at which nitrogen was evolved in the experiments just described, made it possible to measure the velocity of the process. Besides the reactions under (II) and (III), both of which are monomolecular, the following possibilities were to be considered.

Equation IV represents the possible direct interaction of nitromalic acid, either in the normal or the pseudo form, with sulfanilic acid. Equation V is the reaction upon which the method of measurement is based. Of these reactions, (II) and (III) are monomolecular; but (III) is very rapid in comparison to (II), and will therefore interfere to but a small extent. Reaction IV is bimolecular; (V) is also bimolecular, but very rapid.

The results obtained in two series of measurements are given in the following table. Nitromalic and sulfanilic acids were dissolved in cold water, and not placed in the boiling water-bath until all air had been expelled. Carbon dioxide was bubbled through the liquid at the rate of 3 bubbles per second. The gas was not entirely free from air; the amount of air accumulated per hour was determined, and the volume of nitrogen corrected accordingly. The temperature of the azotometer was constant within 1°. Time was recorded from the beginning of heating. This seemed better than making a perhaps dubious allowance for the initial lag. Towards the end of the reaction, the carbon dioxide was absorbed rather slowly making the volume readings uncertain; the later values are not included.

120	37.9	0.0429	0.0214	0.0040	0.0232	0.1095

In the table  $K$  is the value of the constant calculated for monomolecular reaction,  $K'$  for bimolecular. Considering the rather imperfect technique, there is good agreement for  $K$  in the two series, in spite of the considerable difference in concentration. The values of  $K'$  do not agree among themselves and in the second series they become absurd.

The conclusion is therefore justified that the reaction in question is monomolecular, and that Equation IV may be excluded from further consideration. Inasmuch as Reaction III is known to be a very rapid process, the value of  $K$  obtained above may be regarded as substantially indicating the velocity of the structural change.

The formation of oxalo-acetic acid, according to Equation III, was definitely established. From 1.0 g. of nitromalic acid, heated for several hours with a solution of sulfanilic acid, there was obtained by ether extraction 0.15 g. of crude product, melting at about  $120^{\circ}$ ; on recrystallizing from ether and ligroin, the melting point rose to  $180^{\circ}$ .

### Hydrolysis in Neutral Solution.

In order to ascertain the action of nitromalic acid in a solution as nearly neutral as possible, 1.0 g. of sodium nitromalate was dissolved in 100 cc. of water. To this solution, about 1.0 g. of calcium carbonate was added, and the mixture was boiled vigorously, with mechanical stirring, for 2 hours. The volume was maintained approximately constant.

The amount of nitrous acid formed was 8%. The residual solution, free from nitrous acid, gave a copious precipitate with nitron, showing the presence of nitric acid; and the filtrate from this, on evaporation, left a residue which was identified as calcium malate.

### Discussion of Results.

The very considerable variation in the amount of nitrous acid formed from nitromalic acid (from 8% to 80%) under varying experimental conditions, is a convincing illustration of the need of closely defining the working conditions, if a clear picture of the course of an organic reaction is to result. In far too many cases it has been the custom to seize upon the

product that happens to be formed more readily under one set of circumstances, and to regard that product as the main, or even the exclusive, result of the reaction.

In the present case, it would have been quite possible, merely by discontinuing the work, to reach two fallacious conclusions; (1) that the production of nitrous acid is due chiefly to the action of alkali; (2) that alcoholic alkali exerts a greater influence than aqueous.

The truth is that alkali merely catalyzes the formation of nitrous acid, *i. e.*, increases the rate at which it is produced. But at the same time, the alkali catalyzes the normal hydrolysis into *nitric* acid to a still greater extent; and the net result of employing alkali is to diminish the *amount* of nitrous acid, as compared with that formed in acid solution.

It is clear, then, that in the hydrolysis of nitric esters two processes are occurring side by side. Any factor which will hasten one, will make the other lag in comparison. What appears to be an equilibrium, as for instance in the case of hydrolysis by aqueous alkali, is merely a ratio of two rates of reaction. The real action of alcohol, which appears to increase the proportion of nitrous acid, is to slow down the normal hydrolysis into nitric acid.

There can be little doubt that many such false equilibria have served to cloud our understanding of organic reactions. This is conspicuously the case in the so-called molecular rearrangements. Molecular rearrangements resemble the behavior of nitrotartaric and nitromalic acids in that they also involve intramolecular oxidations and reductions. We are not justified in drawing conclusions in this complex field on the basis of a single product which may represent less than half the material originally taken, or even when the product is quantitatively defined but its mode of preparation not varied between sufficiently wide limits.

By the aid of this point of view, it has been possible to secure some interesting and unexpected results along well-worn trails. These will be reported in the near future.

The present studies were begun and completed in the laboratory of the University of California, which with unexampled and unlimited generosity has placed all its facilities at my disposal. It is difficult to express my indebtedness to and gratitude for the courtesies and encouragement extended by Professors G. N. Lewis and E. O'Neill and the entire staff.

### Summary.

1. The preparation and properties of nitromalic acid are described.
2. Nitromalic acid yields a mixture of nitric and nitrous acids when hydrolyzed with aqueous alkali. The percentage of nitrous acid is independent of temperature, concentration or excess of alkali.

3. Hydrolysis in alcoholic solution gives similar results; the percentage of nitrous acid is independent of experimental conditions, but nearly twice as much is formed as in the previous case.

4. The reason for this difference is discussed.

5. It was found that when alkali is excluded altogether, and a substance like sulfanilic acid added, which can take up nitrous acid as fast as formed, the production of nitrous acid is greatly increased.

6. The rate of formation of nitrous acid under the latter conditions was found to be monomolecular.

7. In the hydrolysis of nitric esters two processes occur independently of each other. One is the normal saponification into alcohol (or oxyacid) and nitric acid; the other is isomerization to a nitrous ester, which subsequently hydrolyzes into a carbonyl compound (aldehyde or ketone) and nitrous acid. Each of these reactions proceeds at its own rate under the given conditions.

8. The constant yield of nitrous acid obtained when, for example, aqueous alkali is employed is a false equilibrium. The real constant is the ratio of the rates of the two reactions.

## DIHYDROXY-TARTARIC ACID.

BY ARTHUR LACEMAN.

Received May 18, 1921.

Dihydroxy-tartaric acid was first obtained by Gruber,<sup>1</sup> by the action of nitrous acid on protocatechuic acid. He found that it readily lost carbon dioxide, with formation of tartronic acid; he therefore named the compound carboxy-tartronic acid, and ascribed to it the following structure.

As the formation of an acid of this structure from the oxidation of a benzene ring appeared to support the prism rather than the hexagon formula, the subject was promptly investigated by Kekulé.<sup>2</sup> The latter obtained Gruber's acid from nitrotartaric acid, and was able to reconvert it into tartaric acid by reduction. He explained the formation of tartronic thus: first, loss of carbon dioxide and production of an aldehydo-acid, and second, rearrangement of the aldehydo-acid.

<sup>1</sup> Gruber, *Ber.*, 12, 514 (1879).

<sup>2</sup> Kekulé, *Ann.*, 221, 245 (1883).

Kekulé wrote these equations with the keto groups dehydrated, although as a matter of fact the free acid and its salts all hold at least two mols of water, and should be formulated

as a true dihydroxy-tartaric acid.

Nearly 20 years later, Fenton<sup>3</sup> prepared glyoxyl-formic acid of the formula shown in Equation 2, and found that it did indeed readily pass over into tartronic acid on warming with alkalis, according to Equation 3.

Kekulé's explanation, however, fails to account for the fact that the sodium salt of dihydroxy-tartaric acid also loses carbon dioxide (and water) when heated in the *dry state*, and changes over into sodium tartronate. It is difficult to picture the movements of the sodium atoms in this reaction, on the basis of Equations 2 and 3. Kekulé must have felt this inadequacy, for he devoted much time to a study of the behavior of sodium dihydroxy-tartrate. On one occasion he heated the salt for over 800 hours, with more than 35 weighings. Fenton also made a painstaking investigation of this salt.<sup>4</sup>

A satisfactory explanation of the conversion of dihydroxy-tartaric acid into tartronic acid must, of course, explain equally well the entirely similar transformation of its salt. Such an explanation has been found by noting the similarity in structure between dihydroxy-tartaric acid and benzil.

### Comparison of Dihydroxy-tartaric Acid and Benzil.

Benzil is an  $\alpha$ -diketone; likewise, dihydroxy-tartaric acid is its dehydrated form (2). In fact, dihydroxy-tartaric acid reacts with phenylhydrazine, taking up two mols. Benzil, treated with moderately concentrated alkalis, undergoes two different reactions simultaneously, *viz.*, rupture into benzaldehyde and benzoic acid, and rearrangement into benzilic acid

In the course of the present work, it was found that dihydroxy-tartaric acid, when acted upon by alkalis, behaves quite similarly. Rupture occurs, with production of oxalic and glyoxalic acids; and tartronic acid is also formed together with carbonic acid. Analogy clearly points to a primary rearrangement, in this latter case, to *carboxy-tartronic acid*, which then loses carbon dioxide according to Equation 1.

<sup>3</sup> Fenton and Ryffel, *J. Chem. Soc.*, 81, 426 (1902).

Fenton, *ibid.*, 87, 813 (1905).

<sup>4</sup> Fenton, *J. Chem. Soc.*, 74, 71 (1898). Kekulé (Ref. 2) promised a further investigation, which never appeared in print.

The only essential difference between the behavior of benzil and dihydroxy-tartaric acid lies in the fact that the CO groups in the latter substance are hydrated (cf. 4), and consequently neither water nor alkali is required to be added, so that both rupture and rearrangement may take place upon simple heating, *as in fact they do*. The details will be found in the experimental section of this paper.

The view that the formation of tartronic acid, in the above reactions, is due to a primary rearrangement, finds confirmation in the behavior of diketo-butyric acid.<sup>5</sup> This acid is known only in the form of an ester; when the ester is hydrolyzed by alkali, methyl-tartronic acid results.

It cannot be decided, in this case, whether methyl or carboxyl has shifted, the result being the same in either event. In the case of dihydroxy-tartaric acid, carboxyl is the only group that can shift. Nor is such a movement without analogy. Phenyl-oxypivalic ester, when heated with phosphorus pentoxide shifts a COOR group.<sup>6</sup>

When sodium dihydroxy-tartrate is heated, the shifting group is COONa

and we can thus understand why this salt loses carbon dioxide and water *simultaneously* when it is carefully heated (see experimental section). The carbon dioxide comes from the newly formed ortho-carboxyl group,  $-\text{C}(\text{OH})_2$ , not from the pre-existing, neutralized groups.

The two characteristic reactions which dihydroxy-tartaric acid undergoes simultaneously, *viz.*, rupture and rearrangement (7 and 8), like all simultaneous reactions, may have their relative velocities profoundly influenced by experimental conditions. Weak alkali, acting without undue increase in temperature, gives chiefly rearrangement, and only about 6% of the acid is ruptured. Stronger alkali, aided by heat, will increase the velocity of the rupturing process so that 50% or more of oxalic acid may be found. Heat, without alkali, produces rupture only to the extent of about 1%.

It is a striking phenomenon that rearrangement should be the preferred mode of adjusting the valence or electronic strains in such a complex molecule. It is equally suggestive that rearrangement occurs without the aid or influence of reagents.

## Experimental Part.

**Preparation of Sodium Dihydroxy-tartrate.**—Crude nitro-tartaric acid, as obtained after filtration from the sulfuric acid mixture<sup>7</sup> is stirred into a thin paste with cracked ice, and solid sodium carbonate added until the solution is nearly neutral. If too much has been added, make slightly acid with acetic acid. Under no circumstances must sodium *hydroxide* be used, as both nitro-tartaric and dihydroxy-tartaric acids are decomposed by it. The solution is allowed to stand, preferably immersed in cold water, for about 2 days. Sodium dihydroxy-tartrate deposits slowly, and may be filtered off from time to time. It should be thoroughly washed on the filter, and spread out in a thin layer for rapid drying. Yield, from 100 to 125% of the weight of tartaric acid taken.

As thus obtained, the salt is pure enough for all practical purposes. Previous investigators have failed to note the enormous tendency of this salt to occlude other salts, and their analytical data must therefore be regarded as uncertain. In fact, it may be doubted whether anyone has ever had a *pure* specimen of sodium dihydroxy-tartrate under observation. The best that I have been able to obtain was secured by redissolving 100 g. in just sufficient 3 *N* hydrochloric acid, and precipitating by an equal volume of 3 *N* sodium acetate; the precipitate was washed, first by decantation and then by suction, with 13 liters of water. The washing was continued long after the filtrates failed to give an opalescence with silver nitrate. The air-dried product contained 0.158% sodium chloride. When the hydrochloric acid was replaced by sulfuric, much larger amounts of sulfate were occluded.

**Composition**—The following data were obtained from the product just described, and have been corrected for sodium chloride content:

Loss on heating to ° C.		%.	Ignition residue (Na <sub>2</sub> CO <sub>3</sub> ). %.
150	Very slow	37.85	39.97
150	Very slow	37.85	40.00
165	Slow	37.75	39.95
170	Rapid	37.78	40.02
75	5 hours	2.05	...
96-97	40 hours	2.00	...
96-97	40 hours	2.06	...
Calculated for Na <sub>2</sub> C <sub>4</sub> H <sub>4</sub> O <sub>6</sub> ·2 H <sub>2</sub> O.			2.5 H <sub>2</sub> O.
3 H <sub>2</sub> O + CO <sub>2</sub> .....		37.40	39.48
Na <sub>2</sub> CO <sub>3</sub> .....		40.43	39.10

These data agree well with a water content of 2 mols., and not with 2.5 mols as claimed by Fenton. The rate of loss in weight on heating is very irregular; samples heated side by side varied widely on intermediate weighings.

<sup>7</sup> THIS JOURNAL, 43, 578 (1921).

**Oxidation by Permanganate.**—Fenton has proposed to use sodium dihydroxy-tartrate for the quantitative estimation of sodium, employing the potassium salt as reagent. The precipitated sodium salt is to be oxidized with permanganate. The method offers considerable advantages, as each atom of sodium requires 3 equivalents of oxygen. Fenton found, however, that the actual amount of oxygen consumed was always somewhat less than 3 equivalents. Part of this is accounted for by the occlusion referred to above. There are also irregularities in the action of the permanganate itself, and these were investigated during the present study.

It was found that these irregularities were caused entirely by partial formation of tartronic acid; for whereas solutions of dihydroxy-tartaric acid, freshly made and kept quite cold, used up exactly 3 oxygen equivalents, the same solutions after heating until all the dihydroxy acid had been converted into tartronic acid required but little more than two equivalents. This can be accounted for by the loss of some volatile product, such as formaldehyde or carbon monoxide. Formaldehyde was carefully sought for, but not found.

Quantitative and consistent results were obtained by first oxidizing with permanganate in alkaline solution, then completing in acid with excess of permanganate, using oxalic acid to secure the end point. As a reliable method of determining sodium will have considerable value, a few details will be given here; it is quite likely that the interference caused by occlusion can be minimized or obviated.

Using 0.5000 *N* permanganate solution, direct titration in cold acid solution gave, with samples of about 0.4 g. average weight, 99.8, 95.9, 94.7, 96.1, 93.0 and 94.3%.

Direct titration after boiling with dil. sulfuric acid, gave 62.0, 69.0, 63.7 and 73.5%.

Addition of sodium hydroxide, after boiling sample, before boiling, and together with permanganate followed by boiling respectively, then acidifying after excess of permanganate had acted hot, then finishing with oxalic acid, gave 100.1, 99.8 and 99.9%.

A final series was then made, using 0.1000 *N* permanganate with the following series of manipulations, in order: add dil. sodium hydroxide solution, heat, add excess of permanganate, boil for a few minutes, cool slightly, acidify with dil. sulfuric acid, add 0.1 *N* oxalic acid solution gradually, with boiling, until all of the manganese dioxide has gone into solution, cool slightly, and finish with permanganate. The sample (0.1059 g.) used 24.30-24.35-24.10-24.20-24.10 cc. of permanganate. Calculated, 24.25 cc.

#### **Loss of Carbon Dioxide on Heating Sodium Dihydroxy-tartrate.**—

It was shown above that the salt may be heated for nearly two days without any loss except absorbed moisture, below 97°. No carbon dioxide is given off. At or very near 100°, the substance loses weight again. Kekulé ran his tests "im dampfschrank." At this temperature weeks are required to reach constant weight. At 110° the process had not completed itself after 5 days. At 150° to 160°, a single hour suffices.

In all cases, carbon dioxide makes its appearance simultaneously with water, in agreement with Kekulé's observations. In one test the salt was heated in a boat within a tube passing through a Freas air-bath; a current of washed, dried air traversed the tube and a trap containing lime water. A temperature equilibrium at 105° was established before introducing the boat. The lime water became turbid within 2 minutes.

Attempts were made to measure the ratio of loss of water to that of

carbon dioxide; but owing to the irregularity in the rate of total loss referred to above, no results of value were obtained.

**Formation of Oxalic and Glyoxalic Acids.**—If the rupturing process shown in Equation 7 accompanies the rearrangement of sodium dihydroxy-tartrate into sodium tartronate, the heated salt must be *acidic* in proportion to such rupture, since a new carboxyl group is formed.

Twenty-five g. of salt was heated to 160° for 1 hour, and required 5.5 cc. of 0.1 *N* sodium hydroxide solution to neutralize. This corresponds to 0.55% rupture. Twenty-five g. of salt was next boiled with 100 cc. of water until no more gas was given off; the mixture was allowed to cool and the volume restored, and boiled again. Twelve and one-tenth cc. of alkali was needed to neutralize the acid, equivalent to 1.2% rupture.

The two lots were combined, and phenylhydrazine acetate added. A yellow precipitate formed promptly, insoluble in dil. hydrochloric acid, soluble in sodium carbonate, slightly soluble in ether, easily soluble in alcohol, m. p. 137° (uncorr.), thus identifying it as the phenylhydrazone of glyoxalic acid.

The quantitative estimation of the amount of oxalic acid formed proved very troublesome. This was due to the presence of large amounts of tartronic acid, which also gives an insoluble calcium salt. After the details of the permanganate method for determining tartronic acid (see above) had been worked out, it was possible to use this method on a mixture of calcium tartronate and oxalate, and from the amount of oxygen consumed calculate the proportion of each salt present.

There were some additional difficulties. Calcium tartronate has a different composition when precipitated hot than when formed in the cold. It is also markedly soluble in excess of calcium chloride in the cold, and comes down very slowly when these solutions are boiled. It is therefore necessary to precipitate the mixed acids very slowly and carefully from boiling solutions, and to avoid excess of calcium chloride as much as possible. Nor is this all; the mixed precipitates must be dried at about 170–180°; but calcium oxalate, thus dehydrated, is enormously hygroscopic. Any water present in the sample will decrease the amount of permanganate required, and thus increase the apparent percentage of oxalate.

The results obtained may be summarized briefly. Two samples of sodium dihydroxy-tartrate were carefully warmed with a slight excess of 3 *N* sodium hydroxide solution until dissolved. The yields of oxalic acid were 5.9 and 6.4% respectively. Ten g. of salt was next dissolved in a slight excess of 3 *N* hydrochloric acid, and the solution added quickly and without cooling to a considerable excess of 6 *N* sodium hydroxide solution. The yield of oxalic acid was 9.4%.

Finally, 18 g. of nitrotartaric acid, dissolved in 50 cc. of alcohol, was slowly run into a solution of 15 g. of sodium hydroxide in 150 cc. of alcohol, with water cooling. A yield of 51% of oxalic acid was obtained.

From this last lot, it was possible to secure a small amount of glycolic acid as calcium salt.<sup>8</sup>

<sup>8</sup> Böttinger, *Ber.*, 13, 1932 (1880), has shown that glyoxalic acid is unstable in the presence of alkalis, and goes over into a mixture of glycolic and oxalic acids. He states that the recovery of the glycolic acid is very difficult, which can be confirmed. Cf. Debus, *Ann.*, 338, 322 (1905) for a careful study of this reaction.

### Summary.

1. Dihydroxy-tartaric acid, considered as a diketone, has a structural resemblance to benzil.
2. This resemblance extends to the reactions of the two compounds.
3. The conversion of dihydroxy-tartaric acid and its salts into tartronic acid is an analog of the rearrangement of benzil to benzilic acid.
4. The composition and behavior of sodium dihydroxy-tartrate are discussed.
5. Data are given which will help in the development of the method proposed by Fenton for the direct quantitative estimation of sodium.

### SPIRO-PYRIMIDINES. III. CONDENSATION OF CYCLOPROPANE-1,1-DICARBOXYLIC ESTER WITH UREAS.

BY ARTHUR W. DOX AND LESTER YODER.

Received May 19, 1921.

The preparation of *spiro*-pyrimidines containing 4- and 6-membered hydrocarbon rings has been described in our previous papers.<sup>1</sup> The corresponding 3-membered ring with one of its carbon atoms identical with the 5-carbon atom of barbituric acid was cited as the simplest derivative of this type. Certain difficulties were encountered in preparing such derivatives, hence the discussion was reserved for a later paper. The condensation of cyclopropane-1,1-dicarboxylic ester with urea was readily effected, but the product was so entirely different in its properties from the corresponding cyclobutane and cyclohexane derivatives that it was thought advisable to repeat the work. It has now become evident that a very stable polymer is formed in this reaction, and although its constitution has not been definitely established, it seems advisable to publish the results thus far obtained, for the reason that further work along this line is not contemplated.

#### Preparation of Ethyl Cyclopropane-1,1-dicarboxylate.

This substance has been prepared by Perkin.<sup>2</sup>

In view of the tediousness of Perkin's process and the smallness of the yield, we undertook to apply the method by which we obtained good results in the preparation of cyclobutane-1,1-dicarboxylic ester. According to Perkin there is in this case, much less tendency toward the formation of the open chain tetracarboxylic ester.

<sup>1</sup> Dox and Yoder, *THIS JOURNAL*, 43, 877-84, 1366-71 (1921).

<sup>2</sup> Perkin, *Ber.*, 17, 54-9 (1884); *J. Chem. Soc.*, 47, 808 (1885); *ibid.*, 51, 849-53 (1887).

A mixture of 310 g. of ethylene bromide and 255 g. of ethyl malonate was placed in a flask provided with a reflux condenser and a mechanical stirrer. The flask was immersed in a bath of water maintained at about 80°. By means of a dropping funnel, a solution of 73 g. of sodium in 1100 cc. of absolute alcohol was slowly added during the course of 2½ hours. After the mixture had been heated and stirred for 5 hours the reaction product was neutral to litmus. Most of the alcohol was then distilled, while the solution was stirred continuously. A test portion now showed a slightly alkaline reaction, and hydrochloric acid was added to make the mixture exactly neutral. On the addition of water, the sodium bromide dissolved and a yellow oil separated. The latter was extracted with ether. The yield of crude oil was 237 g. On fractionation 148 g. or 60% of the oil distilled between 200° and 220°. This was fractionated twice and finally yielded 120 g. of a product which distilled between 214° and 216° (corr.) at 748 mm. pressure. Perkin reports a boiling point of 208–10° at 720 mm. Our yield of pure product was 40%, as compared with Perkin's yield of 27–9%.

### Condensation with Urea.

To a solution of 3.7 g. of sodium in 65 cc. of absolute alcohol, 10 g. of ester and 5 g. of urea were added and the mixture was heated for 4 hours in an autoclave at 105°. The white insoluble product was collected on a filter, then dissolved in water and acidified with hydrochloric acid. A voluminous white amorphous precipitate immediately formed. It was insoluble in water, acids and organic solvents, but slowly soluble in caustic alkalis. The yield was 3.5 g. or 42%. On heating the substance it charred at a high temperature without melting. It is precipitated from its alkaline solutions by acetic acid, or by carbon dioxide. Repeated attempts to obtain it in crystalline form by slow neutralization of the alkaline solution or by slow dilution of its solution in conc. sulfuric acid were unsuccessful. The product was invariably amorphous.

*Analysis.* Subs., 0.2, 0.2:  $\text{NH}_3$ , 26.16, 26.13 cc. of 0.1 *N*. Calc. for  $\text{C}_4\text{H}_6\text{N}_2\text{O}_3$ : *N*, 18.18. Found: 18.05, 18.03.

The insolubility and amorphous character of the above product as contrasted with the solubility, crystalline form and sharp melting points of the corresponding cyclobutane and cyclohexane derivatives justify the assumption that a polymerization has occurred. Experiments were conducted to determine whether such polymerization could be avoided by altering the conditions of the condensation. If the polymerization were due to the hydrochloric acid used in liberating the product from its sodium salt, an organic acid should obviate this difficulty. It was found, however, that treatment of the original sodium salt with acetic acid and even with carbon dioxide gave the same product as before. The high temperature of the autoclave or the excess of sodium ethylate did not account for polymerization, since the same product was obtained when the condensation was performed on a steam-bath under a reflux condenser, using 1 mole of sodium instead of 3. In every experiment performed the product obtained was amorphous, insoluble in water, acids and organic solvents, and infusible.

A cyclopropane ring might conceivably polymerize in a number of ways. The simplest possibility is the union of two molecules to form a cyclohexane ring. Such a product would yield on complete hydrolysis of the ureide groupings and loss of one carbon dioxide from each of the carbons carrying two carboxyls, hexahydro-phthalic or hexahydro-terephthalic acid. Again the cyclopropane-*spiro*-barbituric acid might rearrange into vinyl-barbituric acid and then polymerize into a cyclobutane ring with 2 barbituric acid groups attached. The acids which would result from hydrolysis of such a product have not been prepared. Still again, 3 molecules of vinyl-barbituric acid might polymerize with formation of a cyclohexane nucleus. In fact, a number of other possibilities still more remote might be cited.

### Hydrolysis of the Polymer.

Long boiling of the polymer with conc. hydrochloric acid did not alter it. After 3 hours' heating in a sealed tube at 180° with conc. hydrochloric acid, the polymer was recovered quantitatively and the filtrate showed only a trace of ammonium chloride. It was found, however, that hydrolysis can be effected by boiling it with 10% sodium hydroxide for a long time. The substance goes into solution by the time the boiling point is reached, but the evolution of ammonia does not cease until the solution has been boiled for several hours. After complete hydrolysis, as shown by the absence of ammonia and the failure of a test portion, when acidified, to give a precipitate, the solution was acidified with hydrochloric acid and evaporated. Most of the sodium chloride was removed by crystallization and, finally, a sirupy acid was obtained. On heating this in an oil-bath to 200° a copious evolution of carbon dioxide occurred. The residue was then dissolved in water, decolorized with charcoal and crystallized twice. The white crystals, thus obtained, were readily soluble in water and in alcohol, difficultly soluble in ether and in chloroform, and had a strongly acid taste. The melting point was 152° (corr.); 0.1 g. required 11.97 cc. of 0.1 *N* sodium hydroxide for neutralization. The neutralization equivalent was 88. This corresponds to a dibasic acid of molecular weight 176, and is in close agreement with the various acids  $C_8H_{12}O_4$  theoretically possible from polymerization of cyclopropane-carboxylic acid. Of the hexahydro-phthalic acids mentioned above, the only one that approximates this melting point is *cis*-hexahydro-terephthalic acid which melts at 161°. This, however, undergoes a rearrangement into the *trans* acid on heating with hydrochloric acid at 180°. Our acid remained unchanged after this treatment.

### Mono-amide of Cyclopropane-1,1-dicarboxylic Acid.

From the mother liquor of the condensation product, after precipitation of the polymer by acid, 2 g. of a crystalline acid melting at 195° was obtained. It was readily

soluble in water and in alcohol. The nitrogen content and the neutralization equivalent correspond with the calculated values for the mono amide of cyclopropane-1,1-dicarboxylic acid.

*Analyses.* Subs., 0.2, 0.2:  $\text{NH}_3$ , 16.1, 16.1 cc. of 0.1 *N*. Calc. for  $\text{C}_5\text{H}_7\text{NO}_3$ : N, 10.85. Found: 10.99, 10.99.

Subs., 0.1: NaOH, 15.72 cc. 0.1 *N*. Calc. neutral equiv. for  $\text{C}_5\text{H}_7\text{NO}_3$ : N, 129. Found: 127.

#### Di-amide of Cyclopropane-1,1-dicarboxylic Acid.

This was easily prepared by shaking the ester with aqueous ammonia. Five g. of ester and 20 cc. of conc. ammonium hydroxide were placed in a stoppered bottle and shaken 18 hours in a shaking machine. By that time the oily layer had completely disappeared and an abundance of white prismatic crystals had formed. The yield was 3.4 g. or 84%. The substance melts at  $198^\circ$ . It is moderately soluble in water and readily soluble in alcohol.

*Analyses.* Subs., 0.2, 0.2:  $\text{NH}_3$ , 31.61, 31.21 cc. of 0.1 *N*. Calc. for  $\text{C}_5\text{H}_5\text{N}_2\text{O}_2$ : N, 21.80. Found: 21.84, 21.56.

#### Condensation of the Di-amide with Diphenyl Carbonate.

Einhorn and Ladisch<sup>3</sup> prepared veronal by the condensation of diethyl-malonyl amide with diphenyl carbonate at  $200^\circ$ . It was thought that the di-amide described above might condense in the same way, possibly without polymerization of the product. One g. of diamide and 2 g. of diphenyl carbonate were intimately mixed and heated in an oil-bath at  $190$ – $200^\circ$ . A short test-tube was used and this was immersed up to the flange so that the phenol distilled as fast as it was formed. After 9 hours' heating the reaction mixture was extracted with dil. sodium hydroxide solution and filtered from the insoluble phenyl carbonate. When the filtrate was acidified, an amorphous white precipitate was obtained which showed all the properties of the polymer already described.

#### Condensation of the Ester with Guanidine.

A mixture consisting of 1.2 g. of sodium dissolved in 50 cc. of absolute alcohol, 10 g. of ester and 5 g. of guanidine carbonate was heated under a reflux condenser for  $5\frac{1}{2}$  hours. The white amorphous mass obtained was evaporated on a steam-bath to remove most of the alcohol and then taken up with water. An opalescent solution resulted which became more and more cloudy on standing. The addition of acetic acid caused the immediate precipitation of the free base. It was washed thoroughly with water, alcohol and ether, then dried at  $100^\circ$ . The yield was 3.5 g. or 43%. The substance showed the same properties as the corresponding urea derivative except that it was soluble in mineral acids as well as in alkalis.

Subs., 0.2, 0.2:  $\text{NH}_3$ , 37.6, 37.6 cc. 0.1 *N*. Calc. for  $\text{C}_5\text{H}_7\text{N}_3\text{O}_2$ : N, 27.45. Found: 26.32, 26.32.

#### Condensation of the Ester with Thio-urea.

To a solution of 3.7 g. of sodium in 65 cc. of absolute alcohol, 10 g. of

<sup>3</sup> Einhorn and Ladisch, *Ann.*, 359, 184 (1908).

este and 5 g. of thio-urea were added and the mixture heated for 4 hours at  $105^{\circ}$ . The condensation product insoluble in the alcoholic solution was collected on a filter, then dissolved in water. On acidifying the solution with hydrochloric acid, a copious white amorphous precipitate formed at once. It was somewhat soluble in hot water and slightly more soluble in hot alcohol but could not be obtained from either solvent in crystalline form. The yield was 7 g. or 76%.

Subs., 0.2, 0.2:  $\text{NH}_3$ , 22.76, 22.65 cc. 0.1 N. Calc. for  $\text{C}_8\text{H}_{12}\text{O}_2\text{N}_2\text{S}$ : N, 16.47. Found: N, 15.93, 15.85.

Subs., 0.2:  $\text{BaSO}_4$ , 0.2808. Calc.: S, 18.80. Found: 19.28.

### Summary.

1. Cyclopropane-1,1-dicarboxylic ester condenses with urea, guanidine and thio-urea to form stable, amorphous products. From comparison with the corresponding cyclobutane and cyclohexane derivatives it is apparent that these products are polymers.

2. Hydrolysis of the urea polymer, followed by elimination of carbon dioxide, gave a crystalline acid with melting point  $152^{\circ}$  and molecular weight 176 (by titration). Of the acids,  $\text{C}_8\text{H}_{12}\text{O}_4$ , theoretically possible from hydrolysis of a dimer only the hexahydrophthalic acids are known. It is probable that a cyclopropane-1.5-*spiro*-barbituric acid first formed undergoes rearrangement to vinyl-barbituric acid which then polymerizes. The product would then be a cyclobutane-dibarbituric acid, which on hydrolysis and loss of 2 molecules of carbon dioxide would yield cyclobutane-1,2- or -1,3-di-acetic acid, both of which could exist in *cis* and *trans* forms. It is probable that the polymer is not a *spiro* derivative but rather cyclobutane-dibarbituric acid.

DETROIT, MICHIGAN.

## CHANGES IN THE COMPOSITION OF PAPRIKAS DURING THE GROWING PERIOD.

By A. F. SIEVERS AND J. D. MCINTYRE.

Received June 9, 1921.

The change in chemical composition of plants during their growth and development has always been an inviting field of research for the chemist and plant physiologist. Especially is this true in connection with fruits, vegetables and drugs. Much work has been done in this direction, particularly when some definite chemical compound is of predominating influence in determining the quality of the product. As examples, one might mention the development of sugars in the orange, sugar-beet, sweet-corn and sweet potato; citric acid in the lemon; volatile

cils in aromatic herbs; and alkaloids or other active principles in medicinal plants. Such studies are of more than mere scientific interest in that they frequently serve to show at what stage of growth a product should be harvested in order to assure maximum quality and the extent to which lack of care in gathering may affect the general quality of the harvest.

The red peppers, which are widely used as condiments, depend to a varying degree on their pungency as a measure of quality. The investigation here recorded was undertaken for the purpose of tracing the development of the pungent principle and sugar in the paprika, a large fruited variety of *Capsicum annuum*, L. The literature records a great deal of work on the composition of paprikas but the investigations appear to deal mostly with the composition of the several parts of the fruit and the effect of additions of foreign matter on such composition. No systematic study of the fruit from its early formation to its maturity appears to have been recorded.

The paprikas were grown at Arlington, Virginia, and at several intervals of the growing season samples of 6 different sizes of fruit were picked. Since a single plant will bear fruit of all stages of development at one time, the above method appeared to be the most feasible means of securing representative samples of fruit of the several stages. The smallest specimens picked included fruit under 25 mm. in length, while the largest specimens were 100 mm. or more in length. Table I shows the average size and weight of the several samples collected.

TABLE I.

## AVERAGE SIZE AND WEIGHT OF PAPRIKAS AT SIX STAGES OF GROWTH.

Stage.	Length. Mm.	Diameter. Mm.	Weight. G.	Color.
1	less than 25	7.3	1.89	green
2	25 to 37	10.2	3.10	green
3	37 to 50	14.1	7.77	green
4	50 to 75	18.5 <sup>a</sup>	10.77	a few were slightly red
5	75 to 100	17.6	14.86 <sup>b</sup>	about one-half were red
6	more than 100	...	....	all dark red

<sup>a</sup> At this stage the maximum diameter was attained. Upon further development the fruit began to shrink or shrivel somewhat; hence, diameter measurements of the last sample were not taken.

<sup>b</sup> The maximum weight is reached at this stage. The fruit loses considerably in weight as it matures.

The fruit was carefully freed from adhering soil, and after the stems and calyxes had been removed was spread out thinly to dry in a well ventilated room. The dry pods, consisting of shells, placenta and seeds were then ground and passed through a 40-mesh sieve. The samples were analyzed for moisture, ash, alcohol extract, volatile and non-volatile ether extract and reducing and total sugars. The analyses were made according to the Official and Provisional Methods of Analysis, Bureau of Chemistry *Bulletin* 107 (revised), except in the case of the sugars which were extracted accord-

ing to a modified method and then determined by the official gravimetric method. A summary of the results of the analyses is shown in Table II.

TABLE II.

## RESULTS OF THE ANALYSES OF PAPRIKAS AT SIX STAGES OF GROWTH.

Stage.	Mois- ture. %.	Ash. %.	Ether extract.			Alcohol extract. %.	Sugars.	
			Volatile. %.	Non-volatile. %.	Total. %.		Reducing. %.	Total. %.
1	8.46	8.13	0.19	1.95	2.14	18.72	5.81	11.90
2	6.79	7.72	0.17	2.47	2.64	17.03	5.81	13.81
3	7.63	7.57	0.22	4.82	5.04	18.25	6.27	14.72
4	7.19	7.00	0.27	5.24	5.51	19.15	5.90	13.92
5	7.21	6.85	0.24	6.35	6.59	19.24	6.42	13.32
6	7.16	6.78	0.85	8.33	9.18	21.15	8.59	14.39

It will be noted that the ash and ether extract show a definite change through the several stages. The former decreased from 8.13 to 6.78%. The ash was practically all soluble, only slight traces of insoluble matter being present. The total ether extract increased from 2.14 to 9.18% which is a very good indication of the development of the pungent principle. The volatile ether extract, which represents the volatile oil, increased from 0.19 to 0.85%, practically all the increase taking place during the end of the growing period. The alcohol extract shows no definite or decided change and the same may be said about the sugars. The percentage of both total and reducing sugars in the small immature paprikas is exceedingly high as compared with the amount present in the ripe fruit. There are considerable fluctuations in the sugar content during the several stages, due in some measure, possibly, to the tendency of sugars to undergo changes during the drying of the material. The outstanding fact to be noted from these analyses is the increase in the pungency as indicated by the ether extract.

As a rapid means of roughly determining the relative pungency of paprikas, it has been proposed to triturate a definite weighed quantity of the ground pepper in a mortar with sugar, the latter being added a little at a time until a small quantity of the mixture when placed on the tongue does not produce a distinctly pungent taste. This method is, of course, of no analytical value, but when applied to the above 6 samples of paprikas it gave a fair indication of the increase in pungency as the fruit matured. Thus, the quantity of sugar required to mask the pungency of 0.2 g. of the paprika from the first to the last stage was as follows: 0.39, 5.55, 5.52, 7.6, 12.48 and 32.2 g.

In conclusion it may be said that the ether extract is a fairly accurate measure of the maturity of the paprikas, but it is necessary that the normal ether extract of an average sample of such peppers be known for comparison. On the other hand, neither the sugar content nor the alcohol extract changes sufficiently or with such marked regularity as to indicate

the stage at which the fruit was picked. Furthermore, it is evident that even in cases where color is of no consequence and pungency is of first consideration, fully matured fruit must be used to obtain the maximum value.

**DERIVATIVES OF ANTHRAQUINONE. ALIPHATIC THIO-ETHERS,  
 ERS, DITHIO-ETHERS, AND THIO-ETHER SULFONIC ACIDS.**

By E. EMMET REID, COLIN M. MACKALL AND GEORGE E. MILLER.<sup>1</sup>

Received June 10, 1921.

**Introduction.**

The original object in taking up the study of anthraquinone sulfonic acids was to obtain derivatives which could be used for their ready separation and identification. This object was only partially attained but the reaction tried proved interesting and the products obtained appeared worthy of study, so the investigation was shifted from its original purpose and extended in other directions.

On account of the instability of the esters of sulfonic acids the methods used for the identification of carboxy acids<sup>2</sup> were not promising and our efforts were directed to the replacement of the sulfonic groups.

It was known that the sulfonic acid group of  $\alpha$ -anthraquinone sulfonic acids can be replaced by methoxy<sup>3</sup> or phenoxy<sup>4</sup> groups, and that the resulting compounds  $C_{14}H_7O_2.OCH_3$  and  $C_{14}H_7O_2.OC_6H_5$  are crystalline and have definite, though rather high melting points. Hence it was thought that a compound of the type  $C_{14}H_7O_2.SR$  would be of service. *N*-butyl mercaptan was used as being readily available, and it was thought probable that the compound  $C_{14}H_7O_2.SC_4H_9$  would have a low melting point, since sulfur compounds usually melt lower than the corresponding oxygen compounds, and since butyl derivatives are apt to melt considerably lower than methyl, and much lower than phenyl. The desired reaction was found to take place readily, although not quantitatively, when the sulfonic acid group is in the  $\alpha$ -position. The resulting compounds were found to have convenient melting points suitable for the identification of anthra-

<sup>1</sup> The work on the 1,5-compounds is from the Doctor's dissertation (1920) of Colin M. Mackall and that on the 1,8-compounds from that of George E. Miller (1920); the  $\alpha$ -derivatives were prepared by the other author with some assistance from W. S. Hoffman of this Laboratory and A. T. Frascati in the Laboratory of E. I. du Pont de Nemours and Company.

quinone- $\alpha$ -sulfonic acid, and anthraquinone-1,5- and -1,8-disulfonic acids.

Our study has been extended to the derivatives of other mercaptans.

### Historical.

Anthraquinone aliphatic thio-ether sulfonic acids and dithio-ethers may be prepared by the action of aliphatic mercaptans on anthraquinone sulfonic acids in alkaline solution.<sup>5</sup> In this way Bayer and Company prepared anthraquinone-1-ethyl-thio-ether-5-sodium sulfonate and 1,5-diethyl-thio-ether.

Gattermann<sup>6</sup> has shown that the nitro group is replaceable by the alkoxy group when treated with sodium alcoholate, thus,

representing the anthraquinone residue by A. He attempted to carry out the analogous reaction with aliphatic mercaptans in order to obtain anthraquinone thio-ethers, but was hindered by the reduction of the nitro group to the amino group. On the other hand, he found that treatment with alkali aromatic mercaptides readily caused a quantitative replacement of the nitro group with the formation of aromatic thio-ethers.

Gattermann<sup>7</sup> has also prepared anthraquinone aliphatic thio-ethers and thio-ether sulfonic acids indirectly by diazotizing amino-anthraquinones, or amino-anthraquinone sulfonic acids in conc. sulfuric acid. Subsequent treatment of the diazo compound with potassium thiocyanate yielded anthraquinone thiocyanate which on boiling with alcoholic potash gave the mercaptan, which with alkyl halide yielded the thio-ether or thio-ether sulfonic acid. In this way he prepared anthraquinone- $\alpha$ -methyl-thio-ether; anthraquinone- $\alpha$ -ethyl-thio-ether; anthraquinone-1-methyl-thio-ether-5-potassium sulfonate; and anthraquinone-1-methyl-thio-ether-8-potassium sulfonate, thus,

### Outline of Present Investigation.

We have found that anthraquinone- $\alpha$ -sulfonic acid, and the 1,5- and 1,8-disulfonic acids, on heating with aliphatic mercaptans in alkaline solution, react readily to form anthraquinone thio-ethers, thio-ether sulfonic acids, and dithio-ethers, the sulfonic acid groups being replaced in turn.

This reaction takes place with great ease at 100° provided the concentrations are right. The formation of the product from the  $\alpha$ -sulfonate

<sup>5</sup> Bayer and Co., Ger. pat. 224,589.

<sup>6</sup> Bayer and Co., Ger. pat. 75,054.

<sup>7</sup> *Ann.*, 393, 113 (1912).

can be noticed within 2 to 10 minutes after adding the mercaptan. With the 1,5-disulfonate, the separation of the thio-ether monosulfonate begins within a few minutes on account of the very slight solubility of these compounds, while with the 1,8-disulfonate the reaction follows the same course except that the half-way product is much more difficult to obtain, on account of its greater solubility which favors the second stage of the reaction.

Gattermann found that  $\alpha$ -C<sub>14</sub>H<sub>7</sub>O<sub>2</sub>NO<sub>2</sub> reacts readily with potassium thiophenate, KSC<sub>6</sub>H<sub>5</sub>, to give  $\alpha$ -A-SC<sub>6</sub>H<sub>5</sub>. We have endeavored to replace the sulfonic group by using phenyl mercaptan in the same way as the alkyl mercaptans but so far without result, though benzyl and *p*-nitrobenzyl mercaptans react readily under the regular conditions to give excellent yields of the corresponding thio-ethers.<sup>8</sup>

Several experiments have been made in the hope of finding the determining factor. The sodium salt of thioglycolic acid reacts readily but the sodium salt of thiolbenzoic acid does not. In this case the mixture was heated for about 40 hours but no sulfur dioxide was evolved on acidifying a test portion, showing that no sulfite had been formed. The thiolbenzoic acid could be recovered unchanged. This was tried with the 1,5-disulfonate for the same time but with similar negative results; however, there was some indication of a reaction with the 1,8-disulfonate though it had not gone far in 40 hours' heating.

In the hope of finding some compound with about the same acid strength as the aliphatic mercaptans, *m*-aminophenol was tried. This and the sulfonate were boiled with excess of caustic soda solution but there was no evidence of a reaction.

As the  $\alpha$ -sulfonic acid group is somewhat more reactive than the  $\beta$ -group in naphthalene, sodium  $\alpha$ -naphthalene sulfonate was boiled with butyl mercaptan and caustic soda solution, but no reaction took place.

### The Compounds Obtained.

The anthraquinone thio-ethers and dithio-ethers are insoluble in water, slightly soluble in alcohol and soluble in benzene, the solubility in benzene increasing with the size of the alkyl group. When crystallized from benzene they form lustrous crystals varying in color from light yellow to red.

The corresponding sulfones are high melting, slightly yellow crystalline powders.

The anthraquinone-thio-ether sodium sulfonates are moderately soluble in water, the derivatives of the lower mercaptans being more soluble than those of the higher mercaptans and the 1,8 salts being considerably more soluble than the corresponding 1,5 salts. They crystallize from water in

<sup>8</sup> Unpublished work of W. S. Hoffman.

orange or orange-red needles usually containing one molecule of water of hydration. Salts of other bases are highly colored, ranging from yellow through shades of orange to red and are mostly well crystallized.

In the 1,5 series of monobutyl-thio-ether sulfonates, the colors of the barium, strontium and calcium salts run in this order, the barium being deep red and the calcium salt orange, while in the corresponding 1,8 series the order of the colors is reversed.

### Experimental.

**Materials.**—The anthraquinone- $\alpha$ -sodium sulfonate, and anthraquinone 1,5- and 1,8-disodium sulfonates were obtained through the courtesy of E. I. du Pont de Nemours and Company. The methyl mercaptan was generated as required by dropping dimethyl sulfate into warm sodium hydrosulfide, which was prepared by warming crystallized sodium sulfide,  $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ , to about  $90^\circ$  and saturating with hydrogen sulfide. The ethyl mercaptan was prepared in a similar manner using sodium ethyl sulfate. The propyl, butyl and *iso*-amyl mercaptans were prepared by the catalytic method of Kramer and Reid.<sup>9</sup>

### Analytical.

1. **Water of Hydration.**—One-g. samples were exposed to an atmosphere of 50% humidity<sup>10</sup> for 48 hours, then heated to constant weight in a vacuum at  $110^\circ$ , 2 to 4 hours being generally sufficient to remove all the water. Analyses for sulfur and metals were made on the dry samples.

2. **Sulfur.**—Sulfur was determined by means of the Parr bomb,<sup>11</sup> using a 0.2 g. sample and 5 g. of sodium peroxide, with subsequent precipitation of barium sulfate.

3. **Sodium, Barium, Strontium, Calcium, Nickel and Cobalt.**—One-half g. samples were ignited in a platinum crucible until the carbon was burned off as completely as possible. The residue was then evaporated with conc. sulfuric acid, and re-ignited with ammonium carbonate to constant weight. The metal was weighed as the sulfate.

4. **Lead.**—Half-g. samples were ignited cautiously and the residue heated with nitric acid which was evaporated. The residue was evaporated with sulfuric acid and re-ignited with ammonium carbonate to constant weight, the metal being weighed as sulfate.

5. **Copper.**—The copper was precipitated in a faintly ammoniacal solution with hydrogen sulfide. The precipitate was filtered off, dried, ignited and weighed as cupric oxide.

<sup>9</sup> Kramer and Reid, *THIS JOURNAL*, 43, 880 (1921).

<sup>10</sup> A dead air humidor containing 44%  $\text{H}_2\text{SO}_4$  was used to obtain this humidity.

I. Anthraquinone  $\alpha$ -Alkyl Thio-ethers.

One-fifth mole, or 62 g., of sodium anthraquinone  $\alpha$ -sulfonate was heated with 1400 cc. of water containing 0.5 mole of caustic soda and a little more than 0.25 mole of the desired mercaptan. The solubility of sodium anthraquinone  $\alpha$ -sulfonate is given by Dünschmann<sup>12</sup> as 5.1 g. per 100 cc. of boiling water but is diminished by the presence of the caustic soda, so that not quite all of the salt was in solution at the start. The methyl mercaptan was passed through in vapor form while the reaction mixture was heated to near its boiling point and mechanically stirred. The other mercaptans were added in liquid form, sometimes in portions, and the mixtures boiled under reflux. The acid character of the mercaptans is so weak that they readily distil out of the mixture even though it contains an excess of alkali. For this reason some excess of mercaptan was used, particularly of the more volatile ones. With propyl mercaptan 38 g. or 67% of the calculated amount of  $\alpha$ -C<sub>14</sub>H<sub>7</sub>O<sub>2</sub>.SC<sub>3</sub>H<sub>7</sub>, was obtained directly but the filtrate was boiled with 5 g. additional of mercaptan and 10 g. more of the product obtained, bringing the yield up to 85%.

The reaction takes place rapidly and considerable of the product can be observed within 2 to 10 minutes, but the mixtures were heated about 10 hours. The reaction mixtures were filtered hot and the sodium salts washed out with hot water. The anthraquinone-thio ethers were recrystallized from benzene or benzene and alcohol. The yields were good.

Details of several preparations are given in tabular form.

<sup>13</sup> Melting points and analyses by W. S. Hoffman.

Gattermann gives the melting points of the methyl and ethyl derivatives as 208° and 183°.

**Anthraquinone Thioglycolic Acid**,  $C_{14}H_7O_2.SCH_2COOH$ .—A mixture of 31 g. of sodium  $\alpha$ -anthraquinone sulfonate, 11.5 g. of thioglycolic acid, 10 g. of sodium hydroxide and 700 cc. of water was boiled for 11 hours. Crystals, 27 g., separated on cooling. These were filtered off and dissolved in hot water and the free acid precipitated by hydrochloric acid. They were recrystallized partly from nitrobenzene and partly from water and obtained as fine bright yellow needles, m. p. 243°, from which was prepared the sulfoxide, m. p. 239°; Gattermann gives m. p. 250° and 240°, respectively.

## II. Anthraquinone $\alpha$ -Alkyl Sulfones.

The sulfones were prepared by oxidizing the thio-ethers by pouring over them enough fuming nitric acid to dissolve them, and pouring the solution into hot water. They may be purified by recrystallization from acetic acid. When prepared from pure thio-ethers they are obtained pure at the start and their melting points are not raised by recrystallization. All of them are slightly yellowish-white.

Gattermann gives the methyl and ethyl sulfones as melting at 251° and 210°.

## III. Experiments with Sodium $\beta$ -Anthraquinone Sulfonate.<sup>14</sup>

Only preliminary experiments have been made, as it was soon found that this subject must be left for further study. When the sulfonic acid group is in the  $\beta$ -position the replacement by the mercaptan residue takes place with much greater difficulty, if at all; such small quantities, only about 1.3%, of thio-ethers have been obtained, when the experiment is tried in the usual manner, that it is not certain whether the product is produced from the  $\beta$ -sulfonate or is derived from some impurity in it.

Two experiments were made on silver salt, using crude in one case and recrystallized in the other, boiling 1 kg. of the salt for 4 hours with 8 liters of water, 40 g. of caustic soda and 80 g. of butyl mercaptan. The reaction mixture was filtered hot and the residue extracted with chloroform which was then evaporated leaving a red mass that appeared to be a thio-ether. In each case the amount of this was 13 g. No substance of constant properties has so far been isolated from this, or from the supposed sulfone obtained by oxidizing it with fuming nitric acid. Analyses indicate the presence of a monothio-ether, and melting points as well as mixed melting points show conclusively that little, if any, of the  $\alpha$ -thio-ether or its sulfone was present.

Dünschmann<sup>15</sup> separated some  $\alpha$ -sulfonic acid, by recrystallization of the sodium salts, from the products obtained by sulfonating anthraquinone in the usual way without catalyst. Liebermann and Pleus<sup>15</sup> showed that commercial "silver salt" contains some

<sup>14</sup> Preparation of compounds by A. T. Frascati; melting points and analyses by W. S. Hoffman.

<sup>15</sup> Liebermann and Pleus, *Ber.*, 37, 646 (1904).

of the  $\alpha$ -salt but in neither case was any information obtained as to the proportion of the  $\alpha$ -salt except that its amount was small.

We sulfonated 208 g. of anthraquinone with oleum in the usual way and obtained 140 g. of silver salt (42.7%), and recovered 43.8% of the anthraquinone. The mercaptan reaction was tried as above with this silver salt and 1% of a thio-ether resembling that described above was obtained.

One-half of the mother liquor from which the silver salt separated was made alkaline and boiled with butyl mercaptan. The solution was filtered hot and the residue extracted with benzene which left 0.7 g. of a yellow thio-ether.

This melted at 89–92° and had the odor of butyl disulfide. It contained 11.64% of sulfur instead of 10.82% calculated for the butyl thio-ether. It was converted into the sulfone which melted at 150°; mixed with  $\alpha$ -sulfone (m. p. 150°) it melted also at 150°. It contained 9.86% sulfur as compared with calculated 9.77%. Thus it is proved that the mercaptan derivative obtained from the sulfonation mother liquor is the  $\alpha$ -thio-ether, confirming the presence of the  $\alpha$ -acid as a product of the sulfonation of anthraquinone without catalyst. For the total mother liquor 1.4 g. would have been obtained representing 1 g. of anthraquinone or about 1% of that sulfonated. As the mercaptan reaction is not quantitative but usually yields about 80%, we may say that something over 1% of the sulfonic acid groups enter the  $\alpha$ -position.

#### IV. Anthraquinone-1-alkyl-thio-ether-5-sulfonic Acid.

After several preliminary experiments with small quantities a mixture of 300 g. (or 0.61 mol.) of sodium anthraquinone-1,5-disulfonate ( $1,5\text{-C}_{14}\text{H}_8\text{O}_2(\text{SO}_3\text{Na})_2 \cdot 5\text{H}_2\text{O}$ ), 36 g. (or 0.9 mol.) of caustic soda, 120 g. (or 1.0 mol.) of butyl mercaptan (75%) and 4500 cc. of water, was boiled under a reflux condenser for 11 hours, cooled and filtered. The residue was washed with three 800cc. portions of water and dried. From 800 cc. of wash water 1 g. of the barium salt was obtained by precipitation with barium chloride, showing that the sodium salt is soluble in about 1000 parts of cold water. The residue was extracted thrice with hot benzene which removed about 4 g. of the 1,5-anthraquinone-dibutyl-dithio-ether. Hence the yield is 95% of the calculated, while the dithio-ether formed amounts to only 1.6%.

As the monothio-ether-sulfonate, the first reaction product, is only slightly soluble even in hot water, its effective concentration is not enough to push the second reaction. Using ethyl mercaptan where the intermediate product is more soluble about 10% of the dithio-ether was obtained.

The anthraquinone-1-butyl-thio-ether sodium sulfonate obtained as above is a beautiful golden-yellow, with only a slight reddish tinge, closely resembling mosaic gold and we have called it the "gold salt" to correspond with the "silver salt" which is sodium  $\beta$ -anthraquinone sulfonate. Both of these salts lose their metallic sheen when recrystallized. The "gold salt" then appears as glittering orange-red needles.

This salt in a 2% bath dyes<sup>16</sup> unmordanted wool a slightly orange-yellow. It is a bright attractive color and is fairly fast to light but not fast to washing and milling. The bath is exhausted by the wool. The tinctorial power is not sufficient for a valuable dye. With chromium as a mordant, wool is dyed a greenish-yellow. The corresponding ethyl derivative dyes unmordanted wool a pure yellow.

<sup>16</sup> Experiments in the Dye Laboratory of E. I. du Pont de Nemours and Co.

If various metallic salts are added to the bath in which wool is being dyed with the sodium salt, various widely different colors may be obtained; thus a barium salt gives a red and a lead salt a chocolate-brown.

Although the butyl-thio-ether sodium sulfonate is only slightly soluble in hot water it is soluble enough so that other salts, particularly those of the heavy metals and of the aromatic amines, can be prepared from it by double decomposition. For this purpose the sodium salt is dissolved in boiling water and an equivalent amount of a neutral solution of some soluble salt of the desired base is added. The most of these salts are too insoluble to be recrystallized but soluble impurities can be removed by extraction with boiling water. Many such salts containing various alkyls have been thus prepared. The salts are lustrous and many of them highly colored.

The corresponding derivatives with other mercaptans were not so extensively studied. The details of these preparations of the sodium salts are given in tabular form. All of these salts contain one molecule of water.

The strontium and calcium salts also were made of the butyl acid, the strontium salt being anhydrous, (Sr, calc. 10.45; found, 10.40). The calcium salt, unlike the others contains 4 molecules of water of crystallization, showing by analysis 8.12%

of water and 5.09% of calcium compared to 8.35 and 5.07% respectively, by formula. The barium salt is a deep red and the calcium salt an orange-red, while the strontium salt is intermediate.

*Aniline, o- and p-Toluidine Salts.*—These salts were made by adding the corresponding hydrochlorides to the hot, saturated solutions of the sodium salts. All of them are very insoluble and precipitate. They were purified by extraction with hot water. They all separate as fine yellow needles which melt with decomposition at from 250° to 300°. These temperatures are not sharp enough for characterization as had been hoped. The *o*-toluidine salts decompose at lower temperatures than the aniline or *p*-toluidine.

## V. 1,5-Anthraquinone Dialkyl Dithio-ethers.

When the two alkyl groups are the same, these may be obtained directly by heating the sodium 1,5-disulfonate with excess of alkali and mercaptan for a long time. They are always formed to a greater or less extent in the preparation of the intermediate thio-ether sulfonates described above and are obtained by extraction of the crude products with benzene. The diethyl and dibutyl compounds were obtained in this way.

The intermediate monosulfonate may be isolated and purified and the second alkyl group, which may be the same as the first or different, introduced. Of course the mixed thio-ethers must be prepared in this way.

The alkyl thio-ether sodium sulfonate is suspended in about 100 parts of water, containing an excess of caustic soda with the mercaptan, and the mixture boiled. The reaction is slow on account of the low solubility of the sodium salts, particularly of those containing the higher alkyl groups. It is best to introduce the lower alkyl group first. The resulting dithio-ethers are extracted with hot benzene and recrystallized from benzene, or alcohol, or mixtures of the two. The details of the various preparations are given in tabular form.

<i>iso</i> -Amyl	Butyl	10	1000	2	5	41	6.5
	<i>iso</i> -Amyl	10	300	2	5	11	2.5

TABLE IX.

PROPERTIES AND ANALYSES OF 1,5-ANTHRAQUINONE DIALKYL DITHIO-ETHERS. 1,5- $C_{14}H_6O_2(SR)_2$  AND 1,5-RS. $C_{14}H_6O_2$ .SR'.

Alkyls.		Sulfur.			Color and form.
		M. p. °C.	Calc. %.	Found. %.	
Methyl	Methyl	Chars.	21.35	21.03	red needles
	Ethyl	229	20.40	20.35	yellow needles
	Propyl	209	19.53	19.45	orange needles
	Butyl	173.5	18.73	18.50	yellow needles
	<i>iso</i> -Amyl	175	17.99	17.90	orange-yel. leaflets
Ethyl	Ethyl	226.5	19.53	19.40	orange grains
	Propyl	188.5	18.73	18.65	orange grains
	Butyl	156	17.99	17.75	red crystals
	<i>iso</i> -Amyl	152	17.31	17.25	gold-yellow plates
Propyl	Propyl	227	17.99	18.30	orange cryst. powder
	Butyl	175	17.31	16.95	orange prisms
Butyl	Butyl	159.5	16.68	16.65	yellow needles
	<i>iso</i> -Amyl	134	16.09	15.80	orange needles
Di- <i>iso</i> -amyl		158.5	15.55	15.59	yellow needles

Comparing these, we see that the dimethyl compound has the highest melting point and that the melting point is progressively lowered as heavier alkyl groups are substituted for one of the methyls. Gattermann gives the diethyl thio-ether as melting at 230°.

#### VI. 1,5-Anthraquinone Dialkyl Disulfones.

These were prepared just as were the monosulfones by oxidizing the dithio-ethers with fuming nitric acid. They separate as faintly yellow crystalline powders, when their nitric acid solutions are poured into hot water. They are very slightly soluble in most solvents.

## VII. Anthraquinone-1-alkyl-thio-ether-8-sulfonic Acids.

These can be prepared just as the corresponding 1,5 compounds except that it is much more difficult to isolate the sodium salts as, on account of their greater solubility, they react readily with a second molecule of the mercaptan to give the disulfides. In an experiment in which 50 g. of sodium anthraquinone-1-8-disulfonate, 800 cc. of water, 13 g. of caustic soda and 37 g. of butyl mercaptan were heated for 24 hours at 100°, 20 g. or 55% of the dithio-ether was formed.

The details of a number of preparations are given in tabular form.

TABLE XI.

PREPARATION OF SODIUM ANTHRAQUINONE-1-ALKYL-THIO-ETHER-8-SULFONATES.

1,8-RS.C <sub>14</sub> H <sub>6</sub> O <sub>2</sub> .SO <sub>2</sub> Na.H <sub>2</sub> O.

## VIII. 1,8-Anthraquinone Dialkyl Dithio-ethers.

and

The compounds in which the two alkyls are the same are readily obtained directly from the sodium 1,8-disulfonate. Those described below were obtained in this way as by-products in the preparation of the monosulfonates described above. The mixed compounds were prepared as were the corresponding 1,5 compounds. The details are given in tabular form.

TABLE XVI.

## Summary.

It has been found that by heating the sodium salt of  $\alpha$ -anthraquinone sulfonic acid with a mercaptan in presence of caustic soda, the sulfonic acid group is readily replaced yielding an anthraquinone alkyl thio-ether,  $C_{14}H_7O_2SR$ . When two  $\alpha$ -sulfonic acid groups are present these are replaced in succession, yielding first alkyl thio-ether sulfonic acids, 1,5- and 1,8- $NaO_3S.C_{14}H_6O_2.SR$  and then dialkyl dithio-ethers, 1,5- and 1,8- $R'S.C_{14}H_6O_2.SR$ . A large number of compounds have been prepared in which R is methyl, ethyl, propyl, butyl, *isobutyl* and *iso*-amyl.

NORTHWESTERN UNIVERSITY.]

ARSENATED BENZOPHENONE AND ITS DERIVATIVES.<sup>1</sup>

BY W. LEE LEWIS AND H. C. CHEETHAM.

Received June 11, 1921.

## Introduction.

Arsenic in an aromatic nucleus does not interfere with many typical organic reactions. The Friedel and Crafts reaction, however, has found but limited<sup>2</sup> application in organic arsenical chemistry. With a view to determining whether arsenated benzoyl chloride would enter into the Friedel and Crafts reaction, thus yielding a new type of arsenic compound of possible therapeutic value,<sup>3</sup> the work described in this paper was undertaken.

<sup>1</sup> This work was done under a grant from the Interdepartmental Hygiene Board, Washington, D. C., Dr. T. A. Storey, Sec'y.

<sup>2</sup> Lewis, Lowry and Bergeim, *THIS JOURNAL*, 43, 892 (1921).

<sup>3</sup> Therapeutic tests upon new compounds developed under this grant are being conducted by Dr. A. S. Loevenhart, Department of Pharmacology, University of Wisconsin.

It has been found that dichloro-*p*-arsinobenzoyl chloride condenses quite readily with aromatic hydrocarbons and phenyl ethers in the presence of anhydrous aluminum chloride using carbon disulfide as a solvent. When benzene was coupled with the arsenated acid chloride, some benzophenone itself was found among the products of the reaction, and identified by conversion into its oxime, melting at 140°. The formation of benzophenone establishes the course of the main reaction as follows.

When the reaction is too vigorous, de-arsenation of the compound results.

The amount of benzophenone never exceeded 10%, usually running 0.5–1%, while the yield of arsenated benzophenone was 50–60%. That the arsenated product is a ketone is shown by the fact that it reacts with hydroxylamine to form an oxime of the formula  $\text{C}_6\text{H}_5\text{C}(\text{NOH})\text{C}_6\text{H}_4\text{AsO}_3\text{H}_2$ . Furthermore, de-arsenation of the pure product by long refluxing with conc. hydrochloric acid yields benzophenone.

### Experimental.

**Preparation of Benzarsonic Acid.**—Since a considerable quantity of benzarsonic acid (*p*-carboxy-phenylarsonic acid) was required for this work, a comparative study was made of the available methods of preparation. Of the three processes described in the literature, the first involves the oxidation of *p*-tolylarsonic acid by means of alkaline potassium permanganate.<sup>4</sup> The yield is about 60% of the calculated amount, but the process is slow and tedious. A second method uses dil. nitric acid<sup>5</sup> in sealed tubes in the oxidation of *p*-tolylarsonic acid. The yield is practically quantitative, but working in sealed tubes at 150° limits the amount of material, and the high pressure developed breaks a large percentage of the tubes. In the third process, arsanilic acid is diazotized,<sup>6</sup> the cyanogen group introduced through the Sandmeyer reaction, and hydrolyzed to benzarsonic acid. The yield is uncertain and the method expensive.

A more economical and time-saving method was developed as follows. *p*-Nitrobenzoic acid is reduced to *p*-aminobenzoic acid, which is converted to the corresponding arsonic acid by Bart's reaction.<sup>7</sup>

**Reduction of *p*-Nitrobenzoic Acid.**—The method of Jacobs and Heidelberg<sup>8</sup> was

<sup>4</sup> La Coste, *Ann.*, 208, 1 (1881).

<sup>5</sup> Michaelis, *ibid.*, 320, 303 (1902); *Ber.*, 48, 870 (1915).

<sup>6</sup> Bertheim, *Ber.*, 41, 1857 (1908).

<sup>7</sup> Bart, *Ger. pat.* 250,264 and 254,345.

<sup>8</sup> Jacobs and Heidelberg, *THIS JOURNAL*, 39, 1437 (1917).

applied with excellent results in this reduction. Twenty-five g. of *p*-nitro-benzoic acid (technical) is dissolved in a small amount of warm dil. ammonium hydroxide and poured with stirring into a boiling solution of 300 g. of commercial ferrous sulfate crystals in 400 cc. of water. About 100 cc. of conc. ammonium hydroxide is cautiously added, and the boiling continued for 5 minutes. The product is filtered hot after the addition of 50 cc. of ammonium hydroxide. On acidifying the filtrate with acetic acid, *p*-amino-benzoic acid crystallizes in long, light yellow needles; m. p., 186°; yield, 85-90%.

**Conversion of *p*-Aminobenzoic Acid to Benzarsonic Acid.**—The method of Bart is applied as follows. Fifty g. of *p*-aminobenzoic acid is dissolved in 750 cc. of water with 75 cc. of conc. hydrochloric acid and diazotized in the usual manner, using 26 g. of sodium nitrite. The arsenite solution is prepared by dissolving 46 g. of arsenic trioxide in 400 cc. of water with 54 g. of sodium hydroxide. Twenty cc. of 6 *N* copper sulfate solution is now added. The diazo solution is slowly poured into the arsenite-solution with vigorous stirring, the temperature being held at 20°. The alkaline solution is then warmed on the water-bath to 60° until the evolution of nitrogen ceases, when it is acidified with hydrochloric acid. A water-insoluble flocculent precipitate is filtered and discarded. The filtrate on concentrating to 500 cc., cooling, and scratching, deposits colorless crystals of benzarsonic acid. The yield is 50-60%.

**Preparation of Dichloro-*p*-arsinobenzoyl Chloride,**  $\text{Cl}_2\text{AsC}_6\text{H}_4\text{COCl}$ .—Twenty cc. of phosphorus trichloride in 20 cc. of chloroform is slowly added to 25 g. of benzarsonic acid suspended in 100 cc. of cold chloroform. After warming to complete the reaction, 20 g. of phosphorus pentachloride is added at once. When this second reaction has been completed by heating the solution on a water-bath for 10 to 15 minutes, the mixture is fractionated *in vacuo*. Dichloro-*p*-arsino-benzoyl chloride passes over at 190-195° under 20-25 mm. pressure. The yield is 75-80%. In later runs with larger amounts the fractionation was omitted, the material being used directly for the condensation with aluminum chloride.

**Preparation of Benzophenone-*p*-arsenious Oxide,**  $\text{C}_6\text{H}_5\text{COC}_6\text{H}_4\text{As}=\text{O}$ .—Twenty g. of the above acid chloride, dissolved in 100 cc. of dry carbon disulfide, is added to 25 cc. of dry benzene. Twenty-five g. of anhydrous aluminum chloride is then added in 5g. portions to reduce the intensity of the reaction. After warming at 50° on the water-bath for 2 hours under a reflux condenser, the reaction mixture is poured while warm on 300 g. of cracked ice. Ten cc. of conc. hydrochloric acid is added, and the carbon disulfide and excess benzene removed by steam distillation. The reaction flask now contains a clear aqueous solution and a gummy substance which adheres to the walls of the flask. The aqueous solution, which contains the hydrated aluminum chloride and some *p*-carboxy-phenylarsenious acid is decanted and discarded. Four hundred cc. of dil. sodium carbonate solution and 50 cc. of 6 *N* sodium hydroxide solution are added to the flask and warmed to decompose the gummy mass which gradually goes into solution. After filtering and cooling, benzophenone-*p*-arsenious oxide is precipitated in an amorphous condition by dil. hydrochloric acid. The yield is 60%. It is slightly soluble in boiling water, absolute alcohol, benzene, and ether, and easily soluble in warm alkalis.

*Analyses.* Subs., 0.2442, 0.1643: 34.5 cc., 23.3 cc. of 0.0521 *N* iodine solution. Calc. for  $\text{C}_{13}\text{H}_9\text{O}_2\text{As}$ : As, 27.57. Found: 27.59, 27.69.

**Benzophenone-*p*-arsenious Acid,**  $\text{C}_6\text{H}_5\text{COC}_6\text{H}_4\text{As}(\text{OH})_2$ .—The above oxide, after boiling for several hours with a large amount of water, yields a small quantity of fine crystals insoluble in ether or benzene, easily soluble in cold alkalis, and somewhat soluble in absolute alcohol. It is apparently the hydrated oxide.

<sup>9</sup> Poulenc, French pat. 441,215.

*Analyses.* Subs., 0.2681: 46.95 cc. of 0.0389 *N* iodine solution. Calc. for  $C_{13}H_{11}O_2As$ : As, 25.86. Found: 25.57.

**Benzophenone-*p*-arsonic Acid**,  $C_6H_5COC_6H_4AsO_3H_2$ .—The oxide is dissolved in warm dil. sodium hydroxide and a slight excess of the calculated amount of 3% hydrogen peroxide solution added. After warming for 5 minutes, the solution is acidified with hydrochloric acid, which precipitates at once the arsonic acid. From large volumes of boiling water, recrystallization yields lustrous clusters of elongated plates. The yield is quantitative. The crystals soften at 195° but do not melt below 260°. The substance is insoluble in cold water, benzene, and ether, and soluble in alkalis, ethyl alcohol, and warm glacial acetic acid.

*Analyses.* Subs., 0.2214, 0.1579: 27.8 cc., 19.7 cc. of 0.0521 *N* iodine solution. Calc. for  $C_{13}H_{11}O_4As$ : As, 24.51. Found: 24.52, 24.35.

**Oxime of Benzophenone-*p*-arsonic Acid**,  $C_6H_5C(=NOH)C_6H_4AsO_3H_2$ .—Ten g. of benzophenone-*p*-arsonic acid is heated in a slightly alkaline alcoholic solution with 5 g. of hydroxylamine sulfate on the water-bath for 2 hours. After cooling and acidifying with dil. sulfuric acid, the product is recrystallized from hot water, yielding fine colorless needles which do not melt below 260°. The yield is 80%.

*Analyses.* Subs., 0.4611: 12.8 cc. of 0.108 *N* sodium hydroxide (Kjeldahl). Calc. for  $C_{14}H_{13}O_4NAs$ : N, 4.36. Found: 4.20.

Subs., 0.1390: 17.15 cc. of 0.0497 *N* iodine solution. Calc. for  $C_{13}H_{12}O_4NAs$ : As, 23.36. Found: 23.01.

**Mononitro-benzophenone-*p*-arsonic Acid**,  $(NO_2)C_6H_4COC_6H_4AsO_3H_2$ .—Thirty-five g. of fuming nitric acid (sp. gr. 1.5) is added to 4 g. of benzophenone-*p*-arsonic acid and the solution heated on the water-bath for one hour. After dilution with 50 cc. of water, the mixture is slowly evaporated to a thick syrup to expel the nitrous fumes. After two recrystallizations from hot water, 2 g. of fine, light yellow needles were obtained.

*Analyses.* Subs., 0.5385: 12.95 cc. of 0.108 *N* sodium hydroxide (Kjeldahl). Calc. for  $C_{12}H_{10}O_6NAs$ : N, 3.98. Found: 3.65.

Subs., 0.3719: 40.45 cc. of 0.0521 *N* iodine solution. Calc. for  $C_{13}H_{10}O_6NAs$ : As, 21.36. Found: 21.24.

**4-Methyl-benzophenone-4'-arsenious Oxide**,  $CH_3C_6H_4COC_6H_4AsO$ .—This compound is made by substituting toluene for benzene in the procedure described above for benzophenone-*p*-arsenious oxide. The yield is about 50%. Due to its amorphous character, the product is difficult to purify, and arsenic analyses give results 0.5–0.7% low. Its hydrate is made by prolonged boiling with a large volume of water, giving a small quantity of fine, needle-like crystals, soluble in alkalis, insoluble in ether, or benzene, and somewhat soluble in ethyl alcohol.

*Analyses.* Subs., 0.2658, 0.1904: 22.5 cc., 16.05 cc. of 0.0772 *N* iodine solution. Calc. for  $C_{14}H_{13}O_2As$ : As, 24.67. Found: 24.50, 24.40.

**4-Methyl-benzophenone-4'-arsonic Acid**,  $CH_3C_6H_4COC_6H_4AsO_3H_2$ .—Oxidation of the above oxide in warm alkaline solution by means of 3% hydrogen peroxide gives a good yield of the corresponding arsonic acid, which crystallizes from hot water in transparent plates, easily soluble in alkalis, somewhat soluble in ethyl alcohol, insoluble in ether, benzene, etc. The crystals did not melt below 260°.

*Analysis.* Subs., 0.1330: 15.9 cc. of 0.0521 *N* iodine solution. Calc. for  $C_{14}H_{13}O_4As$ : As, 23.43. Found: 23.34.

The condensation of dichloro-*p*-arsinobenzoyl chloride with the phenyl ethers proceeds very smoothly, giving 60–75% yields. In each case the substituted arsenious oxides were found to be amorphous and difficult to purify, and they yielded no

crystalline hydrates. They were therefore oxidized to the corresponding arsonic acids, which are well crystallized and easily purified.

**4-Methoxy-benzophenone-4'-arsonic Acid**,  $\text{CH}_3\text{OC}_6\text{H}_4\text{COC}_6\text{H}_4\text{AsO}_3\text{H}_2$ .—Starting with anisole in place of benzene in the original condensation and oxidizing the intermediate arsine oxide without attempting to isolate it, the corresponding arsonic acid is obtained in 60–70% yield after recrystallization from large volumes of boiling water.

*Analysis.* Subs., 0.3319: 37.4 cc. of 0.0521 *N* iodine solution. Calc. for  $\text{C}_{14}\text{H}_{13}\text{O}_5\text{As}$ : As, 22.32. Found: 22.01.

**4-Ethoxy-benzophenone-4'-arsonic Acid**,  $\text{C}_2\text{H}_5\text{OC}_6\text{H}_4\text{COC}_6\text{H}_4\text{AsO}_3\text{H}_2$ .—Following the same procedure, phenetole gives a 55% yield of the ethoxy-derivative. As the molecular weight increases, the solubility of these arsonic acids in water decreases, so that it becomes difficult to use water as a solvent for recrystallization. Glacial acetic acid or 95% ethyl alcohol is found satisfactory.

*Analysis.* Subs., 0.2193: 24.95 cc. of 0.0497 *N* iodine solution. Calc. for  $\text{C}_{18}\text{H}_{18}\text{O}_5\text{As}$ : As, 21.42. Found: 21.21.

**4-Phenoxy-benzophenone-4'-arsonic Acid**,  $\text{C}_6\text{H}_5\text{OC}_6\text{H}_4\text{COC}_6\text{H}_4\text{AsO}_3\text{H}_2$ .—This arsonic acid is made in 50% yield by using diphenyl ether. It is practically insoluble in water, even at 100°. It is easily crystallized from hot glacial acetic acid or 95% alcohol, giving colorless platelets, which do not melt below 260°.

*Analyses.* Subs., 0.1745: 16.7 cc. of 0.0521 *N* iodine solution. Calc. for  $\text{C}_{19}\text{H}_{15}\text{O}_5\text{As}$ : As, 18.84. Found: 18.69.

Similar compounds have been made from the *ortho* and *meta* homologs of dichloro-*p*-arsinobenzoyl chloride, and will be reported later.

### Summary.

1. It has been found possible to condense dichloro-*p*-arsinobenzoyl chloride with benzene, toluene, anisole, phenetole, and diphenyl ether in the presence of aluminum trichloride with carbon disulfide as a solvent.

2. Properties and directions for preparing the following compounds are given: benzophenone-*p*-arsenious oxide, benzophenone-*p*-arsenious acid, benzophenone-*p*-arsonic acid and its oxime and mononitro derivative, 4-methyl-benzophenone-4'-arsenic acid, 4-methoxy-benzophenone-4'-arsonic acid, 4-ethoxy-benzophenone-4'-arsonic acid, and 4-phenoxy-benzophenone-4'-arsonic acid.

3. An improved method for the preparation of benzarsonic acid has been developed.

**C<sub>18</sub> FATTY ACIDS. II. THE RELATION OF OLEIC AND ELAIDIC ACIDS TO THEIR HALOGEN ADDITION PRODUCTS.**

BY BEN H. NICOLET.

Received June 20, 1921.

One of the most interesting problems in the chemistry of vegetable oils, is the question of the exact constitution of the linolic acids which they contain. Assuming, as is not improbable, that in most<sup>1</sup> oils the acids of the formula  $C_{18}H_{32}O_2$  have their double bonds in the same position, there are nevertheless 4 possible space-isomers (*cis-trans*), and at least two, or perhaps more, of these seem to occur mixed together in each of the commoner oils.<sup>2</sup>

Although at least 2 tetrabromo-stearic acids, and probably 2 tetrahydroxy-stearic acids, have been obtained as derivatives of ordinary "linolic" acid, there is at present no evidence known to the writer which relates a particular tetrabromo acid to a particular tetrahydroxy acid, or which indicates definitely the spatial structure of any one of these derivatives. Takahashi<sup>3</sup> has shown that each of the known tetrabromo acids, when reconverted into linolic acid and again brominated, gives a *mixture* of tetrabromo-stearic acids, in substantially the same proportions as are obtained in brominating the fatty acids of the common oils containing linolic acid. It is therefore evident that a rearrangement has taken place, either in the removal of the bromine to regenerate the double bonds, or in the subsequent addition of bromine to the products thus obtained. Incidentally, as this is the only known method of preparing substantially pure "linolic" acid, it becomes doubtful whether anyone has ever prepared this substance in a form which was not a mixture of at least two, and perhaps more, of the possible isomers.

The present paper describes an attempt, which was unsuccessful, to decide whether this rearrangement took place in the removal, or in the addition of bromine. As there is at present no good method of identifying linolic acid except by the preparation of saturated derivatives,<sup>3</sup> the elimination of bromine from dibromo-oleic and -elaidic acids and its re-addition were studied, as likely to be similar to the corresponding reactions of linolic acid. Lewkowitsch<sup>4</sup> states that oleic acid dibromide, on heating with zinc and alcoholic hydrochloric acid, regenerates oleic acid. It was felt, however, that this result required confirmation, in view of the

<sup>1</sup> For tung oil, at least, this not the case.

<sup>2</sup> E. g., Takahashi, *J. Tokyo Chem. Soc.*, 40, 233-89 (1919); *C. A.* 13, 1583 (1919).

<sup>3</sup> A search is at present being made for suitable solid derivatives.

<sup>4</sup> Lewkowitsch, "Chemical Technology and Analysis of Oils, Fats, and Waxes," Macmillan and Co., London, 1913, Vol. I, p. 184.

known behavior of linolic acid and of the fact that both oleic acid and the two dibromides (oleic and elaidic) are liquids or very low-melting solids, and the identification of the products could accordingly scarcely have been very definite.

In order to obtain more definitely characterizable products, the solid anilides of oleic and elaidic acids were used. The dibromides were obtained both by adding bromine to the anilides in chloroform solution, and by brominating the free acids and subsequently preparing the anilides from the brominated products. The compounds obtained by the two methods were identical.

When oleic acid was converted into the dibromide, treated in the usual way with zinc and alcoholic hydrochloric acid to regenerate the double bond, and then again brominated and converted into the anilide, the only product that could be isolated was oleic-anilide dibromide. As the corresponding elaidic-anilide dibromide is much less soluble, and has a higher melting point, it should have been very easy to recognize, even in rather small amounts, if formed. It is accordingly evident that no elaidic acid was formed.

Similarly, when elaidic-anilide dibromide was boiled with zinc and alcoholic hydrochloric acid, only elaidic anilide was obtained.

It is therefore apparent that when the double bond is regenerated in the dibromides of oleic or elaidic acid (or their derivatives) the original acid is re-formed, without appreciable quantities of the isomeric acid. The cause of this difference between oleic and linolic acid derivatives is still unexplained.

### Experimental Part.

**Oleic-anilide Dibromide.**—Fourteen g. of olive oil fatty acids was dissolved in 30 g. low boiling ligroin, and treated with 1 mol. of bromine in the same solvent, cooling in tap water. The solution was heated on the water-bath for some time with 1 mol. of phosphorus pentachloride, and the phosphorus oxychloride and ligroin were distilled under reduced pressure. The residue was added to 2.5 mols. of aniline, and after standing for some time, the excess of aniline and aniline hydrochloride were removed by washing with dil. hydrochloric acid and with water. The product was crystallized from alcohol after treatment with charcoal. After 6 crystallizations, it melted at 60–62°. Purification from ligroin was considerably more effective, the product melting finally at 67°, after softening at 63°. A sharp melting point could not be obtained.

*Analysis* (Carius). Calc. for dibromo-oleic-anilide: Br, 30.9. Found: 30.0.

The same substance was rather more readily obtained by treating oleic-anilide in 4 parts of chloroform, with 1 mol. of bromine, evaporating the chloroform, and recrystallizing from ligroin. It softened at 64° and melted at 67°, and a mixture of the two products behaved in exactly the same way. It is very soluble in hot alcohol, moderately soluble in the cold, and readily soluble in warm ligroin.

**Bromination of Oleic-anilide in Other Solvents.**—Oleic-anilide in 7 parts of ligroin was treated with 1 mol. of bromine, also dissolved in ligroin. The anilide was not entirely soluble, and apparently an excess of bromine reacted with the soluble portion.

A small amount of a product melting after recrystallization from alcohol at 90–91° was obtained. It was only slightly soluble in cold alcohol, and separated from it as an almost gelatinous mass without apparent crystalline structure. It was, however, readily reduced to a dry powder. The quantity obtained was not sufficient for analysis.

When oleic anilide was treated at room temperature, in chloroform solution, with 4 mols. of bromine (calc. for oleic-tribromo-anilide dibromide), and the solution washed with sodium hydrogen sulfite solution to remove a slight excess of bromine, a different product was obtained, readily soluble in hot alcohol, moderately soluble cold, and melting at 77–78°.

*Analysis* (Carius). Calc. for dibromo-oleic-anilide: Br, 30.9. Calc. for dibromo-oleic-monobromo-anilide: Br, 40.2. Found: 37.15.

The analysis shows the product to be a mixture, and less highly brominated than might have been expected.

**Elaidic-anilide.**—This compound was readily prepared by heating 20 g. of elaidic acid and 15 g. of aniline at 200° for 3 hours in a bomb tube. On recrystallizing from alcohol, the bulky mass of crystals retains an unusually large amount of solvent, so that 3 or 4 crystallizations are necessary. The pure substance melts at 72°, and is readily soluble in hot benzene, moderately soluble cold, very soluble even in cold chloroform, and only slightly soluble in low-boiling ligroin.

**Elaidic-anilide Dibromide.**—This was made in chloroform solution in the same way as the corresponding oleic acid derivative. It is very soluble in chloroform, readily soluble in hot alcohol, slightly soluble cold; and very soluble in hot benzol. The pure substance melted at 88°.

*Analysis* (Carius). Calc.: Br, 30.90. Found: 31.45.

The same substance was obtained as follows. Elaidic acid was converted into the chloride by warming with 1 mol. of phosphorus pentachloride, and the phosphorus oxychloride distilled under reduced pressure. The chloride was taken up in chloroform, 1 mol. of bromine added (with moderate cooling), and after a few minutes, an excess of aniline. The product, after recrystallization from alcohol, was identical with that described above.

**Oleic Acid Regenerated from Oleic Dibromide.**—Twenty g. of oleic acid was brominated in chloroform in the usual manner. The chloroform was distilled and the residue heated for 8 hours under a reflux condenser with an excess of zinc and alcoholic hydrochloric acid. The unsaturated acid thus formed was separated, dried, and converted into the chloride with phosphorus pentachloride, the oxychloride formed being removed under reduced pressure. The chloride was taken up in chloroform and re-brominated, then treated with an excess of aniline. No elaidic-anilide dibromide could be isolated (although it is less soluble and higher melting than the product obtained) the only product isolated being oleic-anilide dibromide, melting, after 3 recrystallizations from ligroin, at 65°.

**Elaidic-anilide from Elaidic-anilide Dibromide.**—Four g. of the dibromide was refluxed for 8 hours with zinc and alcoholic hydrochloric acid. The resulting product was separated and heated for 2 hours with alcoholic potash with the intention of completing the hydrolysis of the anilide. Even after this treatment, however, most of the anilide had resisted hydrolysis. Recrystallized from alcohol and then from ligroin, the elaidic-anilide melted at 67° and was shown by mixing with pure elaidic-anilide to be identical with that substance.

### Summary.

1. The anilides of oleic and elaidic acids and their dibromides have been used to demonstrate definitely that there is no *cis-trans* isomerization

when bromide is added to the double bond and later removed, in the case of either of these acids.

2. This behavior is contrasted with that of linolic acid under similar circumstances.

CHICAGO, ILLINOIS.

### NOTE.

**Correction.**—"Addition Reactions of the Carbonyl Group Involving the Increase in Valence of a Single Atom."<sup>1</sup> Certain typographical errors in three of the formulas given in this article were overlooked. The second

equation on p. 1707, and the first two equations on p. 1708 should read as given above.

JAMES B. CONANT.

### NEW BOOKS.

**John Harper Long.** A Tribute from his Colleagues. Edited by DR. ROBERT H. GAULT, Northwestern University. Northwestern University Press, Chicago, 1921. 70 pp. 15.5 × 22.5 cm. Price \$1.00.

The many friends of the late Professor John Harper Long, for 37 years professor of Chemistry in Northwestern University, will appreciate this feeling portrayal of the man as teacher, investigator, public servant and friend.

This little volume edited by Dr. Robert H. Gault of Northwestern University, contains a chapter by F. B. Dains, entitled "Student, Teacher and Chemist," one by F. Robert Zeit, "A Colleague at the Medical School," another by Ira Remsen on "Dr. Long as a Member of the Referee Board," and an appreciation of the last ten years of Dr. Long's scientific work by Drs. Julius Stieglitz and Paul Nicholas Leach. Dr. Frank Wright reviews

<sup>1</sup> THIS JOURNAL, 43, 1705 (1921).

Dr. Long's activities in connection with Chicago's gigantic drainage problems and the volume concludes with a comprehensive bibliography of Dr. Long's publications, comprising 118 contributions.

There is thus compassed in 70 pages, tastefully arranged, a fitting tribute to a man who did so much for chemistry and education. One outstanding feature of Dr. Long's professional life comes back vividly to the reviewer, a characteristic which indexed well his deep, unselfish interest in his profession, namely, his constant attendance and active, helpful participation in the national and sectional meetings of the American Chemical Society. Even long after his health should have demanded more consideration of self, he gave unstintingly of his time, his counsel and his uplifting ideals, to the organization which had given him his highest honor.

The edition is limited to one thousand, and copies may be obtained through Professor Robert H. Gault, Northwestern University, Evanston, Ill.

W. LEE LEWIS.

**Grundriss der Kolloidchemie.** 6th edition (unchanged reprint of the 5th edition).

By DR. WOLFGANG OSTWALD, Privatdozent at the University of Leipzig. Theodor Steinkopff, Residenzstrasse 12b, Dresden-Blasewitz, Germany, 1921. First half: vi + 329 pp. 60 fig. 16.5 × 24 cm. Price \$2.00.

Colloidal chemistry has developed rapidly during the dozen years that have elapsed since the appearance of the first edition of the "Outline." This development is reflected in the marked expansion shown in this edition, where some 329 pages are required to cover the ground of 140 pages of the first edition.

The mode of treatment, however, is substantially the same as that previously adopted; the subject matter is systematically subdivided in the best Teutonic manner, and each subdivision is thoroughly and carefully discussed in the clear and fluent diction characteristic of the author. The first few chapters of the old edition, dealing with the development of colloid chemistry, have been wholly omitted. It is not too hazardous to predict that, true to hereditary instincts, the author will utilize this product of reproduction by segmentation in an independent volume on the history of colloid chemistry.

The main subdivisions of this first half are: A Practical Introduction; The General Topography of Colloidal Systems; The Relation between the State of Aggregation and the General Properties of Colloidal Systems; The General Energetics of Dispersoids; The Prevalence of the Colloidal Condition, and The Meaning of Colloidal Chemistry; last, The Mechanical Properties of Colloidal Substances.

The paper and type used in this volume leave much to be desired.

ARTHUR B. LAMB.

**Festschrift der Kaiser Wilhelm Gesellschaft zur Förderung der Wissenschaften zu ihrem Zehnjährigen Jubiläum dargebracht von ihren Instituten** (Memorial Volume published by the Kaiser Wilhelm Gesellschaft). Julius Springer, Berlin, 1921. iv + 282 pp. 19 fig. 26 × 18 cm. Price M. 100; bound, M. 130.

This volume celebrating the tenth anniversary of the establishment of the Kaiser Wilhelm Gesellschaft has been issued by its several Institutes. It contains 33 short articles on the most varied topics of Natural Science. These articles have been prepared by leading German investigators. Those of most interest to chemists are:

- Abderhalden.** A Contribution to our Knowledge of Organic Foodstuffs Exhibiting Specific Activity.
- Beckmann.** The Conversion of Grain Straw and Lupine to Foodstuff of Higher Value.
- Einstein.** A Simple Application of Newton's Law of Gravitation to Globular Star Clusters.
- Fischer and Schrader.** A New Hypothesis Regarding the Origin and Structure of Coal.
- Freundlich and Loening.** Protective and Coagulating Action of Hydrophilic Colloids on Hydrophobic Sols.
- Haber.** Science and Economics.
- Hahn.** Regarding Radioactive Disintegration Series and a New Active Substance in Uranium.
- Hofmann and Myron.** The Chemistry of Sodium Phenolate Fusions.
- Polanyi.** The Adsorption of Gases by Solid Bodies.
- Warburg.** The Physical Chemistry of Cellular Respiration.
- v. Wassermann.** Biological Equilibria in Infections and their Medicinal Significance.

The volume is printed elegantly on excellent paper.

ARTHUR B. LAMB.

**Analytische Chemie.** By DR. TH. DÖRING, o. Professor an der Bergakademie Freiberg I. Sa. Theodor Steinkopff, Dresden and Leipzig, Germany. 1921. iii + 97 pp. 15 × 21.5 cm. Price \$0.60.
